Abstract

Objectives

In many South Asian communities, the majority of women are married during adolescence and reproduce before 20 years. Early reproduction may adversely affect maternal nutrition and linear growth, however whether early marriage has similar effects is unknown. Shorter women might also be preferentially chosen for earlier marriage. We hypothesised that early marriage and early pregnancy may each be associated with women's shorter height, independent of any selection effects.

Materials and Methods

We analysed cross-sectional data on 7,146 women aged 20-30 years from rural lowland Nepal. Linear regression models tested associations of early marriage and early reproduction with height, adjusting for women's education and husbands' characteristics (education and wealth) that might index preferential selection of short young women for marriage.

Results

Median ages at marriage and first pregnancy were 15 and 18 years respectively, with 20% pregnant <16 years. Both early marriage and early pregnancy were independently associated with shorter stature, accounting for a decrement of 1.4 cm, which decreased to 1 cm after adjusting for women's education. **Effects of early marriage and reproduction** persisted after adjusting for the tendency of poorer and less educated men to marry young and short women, indicating a role for social selection.

Discussion

The decrements in height associated with early marriage and reproduction are indicative of broader adverse effects on maternal metabolism during a 'critical period' of growth and maturation in the life-course of women. Although the magnitudes of effect are relatively small, they affect large numbers of women in this population.

Keywords: Adolescent marriage; early pregnancy; height; social selection; rural lowland Nepal

INTRODUCTION

In South Asia, there is a transactional nature to marriage, with its timing generally decided when the perceived costs of maintaining a daughter and investing in her education in the natal home exceed the benefits of her unpaid labour (Human Rights Watch, 2016). The prospective marital family's demand for a wife of a particular age and education level also influences her age at marriage (Human Rights Watch, 2016). Whilst both households stand to gain from this transaction, early (defined by the United Nations as <18 years (UN General Assembly, 2014)) marriage may adversely affect the health and human capital outcomes of both the woman and her subsequent children (Godha, Hotchkiss, & Gage, 2013; Kim, Mejía-Guevara, Corsi, Aguayo, & Subramanian, 2017; Raj et al., 2010).

Age at marriage may then have implications for maternal height, which in turn affects offspring's health. Across low and middle-income countries (LMICs), for example, maternal stature was inversely associated with offspring mortality risk, and the prevalence of underweight and stunting in infancy and childhood (Addo et al., 2013; Monden & Smits, 2009; Özaltın, Hill, & Subramanian, 2010). Studies from the Gambia have likewise found that in comparison to shorter women, taller women had later first births, fewer stillbirths, larger offspring and lower infant mortality (Allal, Sear, Prentice, & Mace, 2004; Sear, 2010). Physiologically, shorter women have **smaller pelvic dimensions**, and this may contribute to intrauterine growth restriction and low birth weight **in the next generation** (Kozuki et al., 2015; Shirley, Cole, Arthurs, Clark, & Wells, 2019).

Although adult height is a highly heritable trait (Fisher, 2019; Perkins, Subramanian, Davey Smith, & Özaltın, 2016; Silventoinen, Helle, Nisén, Martikainen, & Kaprio, 2013) it is also influenced by environmental and developmental factors (NCD Risk Factor Collaboration, 2016; Silventoinen, Kaprio, Lahelma, & Koskenvuo, 2000), particularly those acting during early periods of development (Bogin, 1999; Perkins et al., 2016; Tanner, 1992). While much attention has been paid to 'critical windows' in foetal life and infancy, later developmental periods may also be important. For example, adolescent girls in rural Gambia showed substantial catch-up in height between the ages of 12 and 18 years (Prentice et al., 2013). Environmental stresses acting during adolescence might therefore constrain adolescent growth.

Addressing the association between early marriage and height builds on substantial prior work in the discipline of anthropometric history, which explicitly sought to use data on anthropometric outcomes to improve understanding of the **adverse experiences** of marginalised groups (Komlos, 1991, 1994; Steckel, 1995). **Assessing trends in height over time to indicate changes in living conditions is particularly important for** those low in social hierarchies, because conventional markers of living standards (e.g. wages **or wealth**) have little relevance (Tanner, 1990). **For example, a study of 19th century child factory workers interpreted girls' lower height-for-age score compared to boys as a marker of discrimination, potentially reflecting girls' higher susceptibility to disease, undernutrition, and the arduous physical nature of their work in both the factory and home (Horrell & Oxley, 2016). In contemporary patriarchal societies, conversely, women have negligible opportunity to participate in the wage economy, and it is the norm for women to marry and reproduce before linear growth is completed. In both contexts, analysing anthropometric variability can provide a unique opportunity to explore asymmetric power relations in society and within families, which may have implications for health outcomes (Wells, 2016).**

1
2
3 Previous research has indicated that early age at reproduction may adversely impact women's
4 growth. For example, Rah et al found that sub-optimal diets during pregnancy and lactation
5 exacerbated Bangladeshi girls' poor nutritional status and hindered their linear growth (Rah et
6 al., 2008). These authors estimated that the cessation of linear growth due to early pregnancy
7 might result in an overall decrement of between 0.6 and 2.7 cm in attained height among 12 to
8 19 year old girls (Rah et al., 2008). In a similar study in Mexico City, pregnant adolescents
9 showed no change in height between 20 weeks of gestation and 1 month post-partum, whereas
10 non-pregnant adolescents matched by socioeconomic level, chronological age, menarche age
11 and BMI gained 0.9 cm (Casanueva, Roselló-Soberón, De-Regil, Argüelles, & Céspedes,
12 2006). Mechanistically, early reproduction may generate 'competition' for nutrients between
13 the mother and foetus, and this may impair the growth of both mother and child (Allal et al.,
14 2004; Scholl, Hediger, Schall, Khoo, & Fischer, 1994; Sear, Allal, & Mace, 2004; Stulp &
15 Barrett, 2016). These effects may be exacerbated in high-pathogen environments where
16 infectious disease is largely untreated, as more energy may be allocated to immune defence,
17 reducing its availability for growth (Wells & Stock, 2020). However, evidence on the
18 association of early pregnancy with height remains sparse.
19
20
21
22

23 **Beyond these trade-offs, reproduction also reduces the allocation of energy to other metabolic**
24 **functions such as defence, due to immune suppression, particularly in resource limited contexts**
25 **(Jasienska, 2009). For example, in countries with high malaria burden, the frequency and**
26 **severity of malaria is greater during pregnancy and early postpartum than before pregnancy**
27 **(Diagne et al., 2000). Another component of defence is the stress response, which also has high**
28 **energy costs, thereby reducing energy availability for other functions. For example, compared**
29 **to lactating mothers in a control group, those who participated in a relaxation intervention had**
30 **lower stress scores, lower breastmilk cortisol, and higher infant breastmilk intake and weight**
31 **gain (Shukri et al., 2019).**
32
33

34
35 Aside from early reproduction, whether early marriage is associated with shorter maternal
36 height appears not to **have** been considered. In South Asia, marriage generally precedes
37 childbearing and represents a cultural gateway to reproduction, and a **substantial** proportion of
38 women are married during adolescence (MacQuarrie, 2016). In 2018, for example, 30% of
39 women across South Asia aged 20-24 years had married <18 years and 8% <15 years
40 (UNICEF, 2020).
41

42
43 This paper therefore aims to investigate the independent associations of early age at marriage
44 and first reproduction with women's height, in a cohort of women from rural lowland Nepal.
45 Our models adjust for women's education as a potential confounder. Education is the only
46 marker of socio-economic status in our dataset that reflects **a** woman's experience growing up
47 in the natal household. Women with no or little schooling might be more likely to marry young,
48 while the same educational traits might indicate family environments less favourable to growth
49 (e.g. greater food insecurity or poorer sanitation, increasing exposure to infections). We further
50 aim to investigate whether such associations are independent of **husbands'** characteristics
51 (education, marital household wealth), which might contribute to selection effects (poorer men
52 might marry women who are both younger and shorter).
53
54

55 ***Women's early marriage and growth***

56 Beyond any mediating role of early reproduction, there are a number of different mechanisms
57 through which early marriage may be associated with women's shorter height. While previous
58 work has addressed the prospective association of adult height and the likelihood of women
59
60

1
2
3 subsequently getting married and the timing of their marriage (Murasko, 2020; Smits &
4 Monden, 2012; Yamamura & Tsutsui, 2017), our interest here is on the impact of marrying
5 before adulthood on final height.
6

7
8 First, poverty and socio-cultural practices discriminating against women may result in
9 decreased nutritional intake and poor growth of those women who are likely to be married early
10 (Aurino, 2017; Bajracharya & Amin, 2012). An analysis of Demographic Health Survey (DHS)
11 data on married women aged 25-49 years from 54 LMICs found that on average, compared to
12 the poorest quintile of wealth in the marital household, those in the first and second two richest
13 quintiles were 2.0 and 1.0 cm taller respectively (Subramanian, Özaltın, & Finlay, 2011).
14 Similarly, compared to uneducated women, those with primary or secondary education were
15 0.16 and 1.33 cm taller (Subramanian et al., 2011). Since poverty may be an important correlate
16 of early marriage (Bajracharya & Amin, 2012; Samuels, Ghimire, Tamang, & Uprety, 2017),
17 it may also contribute to shorter height among those who marry early, though some historical
18 studies have found the opposite (Baten & Murray, 1998).
19
20

21
22 Second, there may be a genetic link between early puberty and shorter height. Girls who
23 undergo puberty early tend to achieve shorter final height, reflecting their earlier growth
24 cessation (Ong et al., 2009). In turn, studies suggest girls who experience puberty early may
25 be more likely to marry earlier, as visible signs of sexual maturity may send a social signal for
26 the readiness for marriage (and childbearing) (Chari, Heath, Maertens, & Fatima, 2017; Raj et
27 al., 2015). However, a study from Brazil found that poor early growth was associated with later
28 puberty, but nevertheless with early childbearing (Wells, Cole, et al., 2019).
29
30

31
32 Third, early marriage might lead to the constraint of linear growth through psychosocial stress.
33 During late adolescence, girls can gain between 5 and 7.6 cm (Spear, 2002; Viner et al., 2015),
34 while in under-nourished populations, linear growth may continue beyond 20 years of age in
35 order to recover from growth faltering in early life (Rah et al., 2008; Satyanarayana, Nadamuni
36 Naidu, Swaminathan, & Narasinga Rao, 1981; Wells, Wibaek, & Poulas, 2018). In children,
37 seminal work in German orphanages found that, despite abundant food provision, harsh and
38 unsympathetic treatment caused distress and curtailed linear growth (Widdowson, 1951). More
39 generally, growth in early life is widely recognised to reflect social conditions (Tanner, 1992).
40 Little is known about this scenario in adolescents, however early marriage could exacerbate
41 psychosocial stress. In a study in rural India, for example, early marriage, social isolation and
42 adapting to new behaviours of the marital household increased distress and under-nutrition,
43 partly because young married women chose to eat less because of their low mood (Chorghade,
44 Barker, Kanade, & Fall, 2006). Similarly, studies from Nepal have found social dynamics at
45 meals such as young wives eating last and eating less than other family members may impact
46 on nutrition (Clarke et al., 2014; Harris-Fry et al., 2018).
47
48

49
50 Fourth, an association between early marriage and growth might also emerge through social
51 selection. In South Asian societies, covariance between husbands' and wives' characteristics
52 emerges from household choices in arranged marriage agreements, potentially reflecting
53 assortative mating by wealth or education (Smits, Ultee, & Lammers, 1998), though it might
54 also relate to direct concerns regarding height as a marker of social status, as reported in
55 Pakistan (Ahmad, Gilbert, & Naqui, 1985). A study on marriage markets in India found that
56 women who were taller than average had a greater likelihood of marrying overall, and also of
57 marrying after 16 years of age (Smits & Monden, 2012). Both this study from India and another
58 study from Italy also found taller women were more likely to pair with more educated husbands
59
60

with a better labour market position (Ponzo & Scoppa, 2015; Smits & Monden, 2012). Theoretically, husbands seeking young brides might also directly seek short women, or indirectly pair with them by being unable to marry tall women. This might occur for example if poor men, also relatively short, preferred young wives and selected women from similar socio-economic backgrounds **who were also short**.

MATERIALS AND METHODS

Study context

This analysis is based on **secondary analysis of** data from the Low Birth Weight South Asia Trial (LBWSAT). The trial was approved by the Nepal Health Research Council and University College London ethics committees. Written informed consent was obtained from participants. This cluster randomised controlled (non-blinded) trial was conducted in the southern areas of Dhanusha and Mahottari districts, in Province 2 of the lowland Terai zone of Nepal. All married women and girls between the ages of 10-49 residing across 80 Village Development Committees (VDCs) were invited to take part in the trial. The main exclusion criteria was that neither they nor their husbands had undergone operative family planning (Saville et al., 2018, 2016). Between Dec 2013 and Feb 2015, 64,000 eligible women consented to menstrual monitoring and 24,682 pregnant women were recruited into the trial (Saville et al., 2016).

The main aims of LBWSAT were to assess the impact of pregnancy interventions on birth weight and infant growth (weight-for-age z-score, from 0–16 months). VDC clusters were randomly assigned to one of four interventions: (a) a behavioural change Participatory Learning and Action approach implemented through women's groups (PLA), (b) PLA and unconditional cash transfers provided to **pregnant** women, (c) PLA and a fortified blended food supplement given to **pregnant** women, or (d) Government of Nepal health services, which functioned as the control group. Data were collected by trained fieldworkers using oral questionnaires administered through smartphones.

Variables analysed

Our dependent variable is height (cm). Our value for height collated measurements made either during early or late pregnancy, or during the postpartum period where pregnancy measurements were missing. We used height rather than weight as a marker of growth because weight may change substantially in association with pregnancy and other stimuli or stresses.

Our primary independent variables are women's age at marriage and **at first pregnancy**. **Not every pregnancy necessarily resulted in a live birth**. Women's marriage age and age of first pregnancy were recorded as integer values in running years, which were then converted to completed years (running years minus 1) during analysis. **This is because most people count age in the year in which they are running rather than in completed years in this setting**. Age at marriage was coded into five groups: 10-14 years, 15 years, 16 years, 17 years and ≥ 18 years. Age at first pregnancy was coded into three groups: <16 years, 16-17 years and ≥ 18 years.

Educational attainment (highest class completed in school) of both the wife and the husband was coded into four levels based on the structure of the education system in Nepal and also based on the distribution of data in our sample: none, primary (1-5 years), lower secondary (6-8 years) and secondary or higher (≥ 9 years).

1
2
3 Marital household assets reflect the context that women marry into, and also where the
4 allocation of food, psychological well-being and the timing of pregnancy are negotiated. Our
5 analyses used quartiles of marital household asset score, with 1 being the poorest and 4 being
6 the richest. The household asset score was derived using principal component analysis based
7 on the ownership of consumer goods including non-biomass fuel use, colour television,
8 motorbike or computer, **land ownership and** household infrastructure: drinking water source,
9 access to toilet facilities and electricity, roofing, walls and flooring materials. The first principal
10 component had positive factor loadings for all 12 variables, accounting for 30.2% of the
11 variability, compared to 10.5% and 8.5% from the second and third principal components
12 respectively. We therefore used the first principal component as a marker of wealth.
13
14

15 *Adjusting height for age*

16 Since our interest is in examining how events in the past (marriage and first pregnancy) may
17 be captured in women's phenotype (adult height), we focused on the 20 to 30-year age group.
18 The lower age cut-off of 20 years was selected because this is when linear growth in this
19 population is on average completed. **In Supplementary Figure S1, loess scatterplot smoothers**
20 **were fitted to explore associations between** women's age and height for married women aged
21 14-30 years. The scale on the graph has been adjusted to **show ages 16-24 years only, in order**
22 **to** emphasise the age at which height shows an age-associated inflexion in this population.
23 **Results** show an increment in height up to the age of 20 years. Specifically, height increased
24 by 0.07 (95% CI -0.05, 0.19, $p=0.287$) cm per year between the ages of 14-19 years, and
25 declined by -0.07 (95%CI -0.12, -0.03, $p=0.002$) cm per year between 20-30 years. The upper
26 age cut-off for the sample was selected as 30 years because of small numbers above this age.
27
28
29
30

31 **In Supplementary Figure S2, loess scatterplot smoothers were fitted to explore associations**
32 **between women's age and height for the selected sample of women aged 20-30 years used in**
33 **our analysis. Results** show a weak negative linear association between age and height for
34 women aged 20-30 years, indicating a secular trend whereby more recent birth cohorts are
35 taller than older cohorts. **This cohort effect in height has been found in South Asia (NCD Risk**
36 **Factor Collaboration, 2016; Subramanian et al., 2011).** To adjust for this association, we
37 standardized our outcome variable height by age, by taking the residuals from a regression of
38 height as the dependent variable against age as the independent variable.
39
40

41 *Sample selection*

42 The flowchart in **Supplementary Figure S3** illustrates the criteria used to select $n=7,146$
43 women aged 20-30 years for this analysis. Briefly, the study recruited 24,682 women into the
44 trial. First, we excluded women who had more than one pregnancy during the trial ($n=408$), to
45 ensure they were not double-counted in our analyses. Second, we excluded women who were
46 missing data on age ($n=36$), and who were either <20 ($n=9,950$) and >30 ($n=1,098$) years of
47 age. We excluded the younger women because they are likely to be growing still. Factors
48 affecting age at marriage of older women may have also differed from those in the 10-year
49 cohort we selected, and may be less relevant to current issues around age of marriage and first
50 pregnancy.
51
52
53

54 Third, we excluded women missing data on their marriage age ($n=1,883$), and those who either
55 married very young (<10 years of age, $n=99$), or at an older age (>22 years of age, $n=67$)
56 because of small numbers. These women were likely to be different than most other women in
57 Province 2 of Nepal, who married at the median age of 16.5 years (Ministry of Health and
58 Population, Nepal, New ERA, & ICF International, 2017). Furthermore, in the Maithili-
59
60

1
2
3 speaking Madhesi population of our study, married girls are not likely to move to their
4 husbands' home until attaining menarche (Gram et al., 2017). Therefore, for the very young
5 group, it was difficult to test whether marriage or first pregnancy age was associated with their
6 height.
7

8
9 Fourth, we excluded women with missing data on first pregnancy age ($n=128$), and with
10 unusual timing of first pregnancy (either before marriage ($n=3$), or ≥ 12 years after marriage
11 ($n=99$)). In 2016, women aged 25-49 years in Province 2 had median age at first birth of 19.2
12 years (Ministry of Health and Population, Nepal et al., 2017).
13

14
15 Fifth, we excluded women who were missing data on marital household assets ($n=3$), or the
16 location of the home where they were measured ($n=62$), and if they were measured in their
17 natal or other home ($n=1,461$).
18

19
20 Sixth, we excluded women with missing data on height ($n=2,239$). **Supplementary Table S1**
21 shows small differences between women with missing and available data. The small magnitude
22 of the difference is not expected to bias our results.
23

24 *Statistical methods*

25 We first describe characteristics of our sample using frequencies and proportion (%), mean and
26 standard deviation (SD, for height only), or median and interquartile range (IQR) because of
27 the skewed distribution of age, timing and asset data. To test for biases in continuous values of
28 characteristics between women with missing and available data on height, we use non-
29 parametric K samples analysis of variance (Kruskal-Wallis test) to test for homogeneity of
30 location. Spearman's coefficients describe correlations between continuous values of the
31 variables used in analyses.
32
33

34 We then compare mean and standard error (SE) of women's height, age at marriage and first
35 pregnancy by women's education. **We also ask whether poorer and less educated men are more**
36 **likely both to marry younger and shorter wives, which would indicate a role for social selection**
37 **in the correlation between women's marriage age and height. We compare mean (SE) of**
38 **women's height, age at marriage and age at first pregnancy by both husbands' education level**
39 **and marital household assets. We test for trends in these associations using linear regression.**
40 These analyses test whether, as expected, **these variables are** potential confounders of the
41 association between marriage age and height.
42
43

44
45 Next, we fit four Ordinary Least Squared (OLS) Linear Regression models in order to assess
46 the separate, and combined (or independent) associations of **age-standardised height residual**
47 with women's age at marriage (Model 1), women's age at first pregnancy (Model 2), and their
48 combined associations (Model 3). Then, we introduce women's education (Model 4), as a
49 potential confounder of the association between height and age at marriage **or** first pregnancy.
50
51

52 In addition, we present these OLS linear regression models for the uneducated women only,
53 because they comprise a substantial proportion of our sample, and because in this group,
54 women's height is entirely unconfounded by schooling.
55

56 We then further adjust our regression models of women's height for these two markers of the
57 husbands' education and wealth, in order to take into account any social selection effects. **To**
58 visualise these associations, we present 3D plots of the potential interactions between height
59
60

and women's marriage age, pregnancy age and husbands' education level and assets. These 3D plots illustrate the combined social gradients in height associated with other factors.

In all of these models, we use women marrying at ≥ 18 years, and having their first pregnancy at ≥ 18 years, as the respective reference groups as we want to ascertain whether earlier timing of these events is associated with lower height. Selecting a group with later marriage or first pregnancy is not possible in this population due to small numbers, since early marriage and reproduction represent the norm. We use 'no education' and 'poor' households as the reference groups because we want to know whether attaining higher levels of these socio-economic characteristics benefited women's height.

We report regression coefficients and their 95% confidence intervals (CI). We use the variance inflation factor (VIF) to test for multicollinearity. Although we report the adjusted R^2 , multiplied by 100 to describe the proportion of the independent variable's variance explained by the inclusion of each predictor variable in each model, we do not discuss these values because our interest is in understanding the magnitude of the effect of the exposure at the population level, rather than to predict the height of individual women. Tests are conducted at a 5% two-sided significance level.

We also fit regression models adjusting for (unobserved) variability between the 80 geographic clusters, and trial arms, but as these factors have negligible effects and do not change our results substantively, we do not report the results.

Analyses are performed in Stata IC 15.1 (Stata Corp., College Station, TX) and SPSS 26 (IBM Corp., Armonk, NY).

RESULTS

Description of sample

Table 1 describes the characteristics of our sample. Mean height was 150.4 cm (SD 5.4). The median marital household asset score was -0.41 (IQR 2.4). About 37% of women had married during childhood, at ages 10-14 years, 51% during adolescence (ages 15-17 years) and 12% at ages ≥ 18 years. About 20% of women had their first pregnancy at < 16 years, 33% at ages 16-17 years and 48% ≥ 18 years. Almost 71% of women and 51% of husbands were uneducated compared to 12% and 22% with ≥ 9 years of schooling respectively.

Table 1 near here

Testing whether education and marital assets are potential confounders

Table 2 explores if women's height, their age at marriage and first pregnancy increase in association with their own higher educational attainment, as well as their husbands' education and the marital household asset score. The results show statistically significant trends, with each of women's height, age at marriage and age at first pregnancy increasing in association with both women's and husbands' education, and with the marital household asset score.

Table 2 near here

Quantifying the association between marriage and first pregnancy age with height

The OLS linear regression models show the associations of women's height with their marriage age, and age at first pregnancy, adjusting for women's education.

Table 3 near here

Table 3, Model 1 shows that relative to marrying at ≥ 18 years, marrying at 10-14 years was associated with a decrement in height, of -1.20 (95% CI -1.61, -0.79) cm, and marrying at 15 and 16 years -0.97 (95% CI -1.41, -0.54) and -0.50 (95% CI -1.01, 0.00) cm respectively. The association of marrying at 17 years with height did not reach statistical significance (-0.49 cm, 95% CI -0.99, 0.00, $p=0.052$). **Model 2** shows that in comparison to having the first pregnancy at ≥ 18 years, women having their first pregnancy at < 16 years paid the biggest penalty in height, of -0.87 (95% CI -1.21, -0.53) cm. First pregnancy between 16-17 years was also associated with lower height of -0.34 (95% CI -0.62, -0.05) cm.

Model 3 shows that when considered in combination, early marriage at 10-14 years and 15 years had a stronger negative association, at -0.99 (95% CI -1.48, -0.51) cm and -0.92 (95% CI -1.40, -0.44) cm respectively, with height, than early pregnancy. However, the independent negative association of early pregnancy at < 16 years (-0.42 cm, 95% CI -0.84, 0.00) with shorter height shows it also mattered. Neither marrying nor first pregnancy at 16-17 years reached statistical significance. The decrease in the coefficients in Model 3 compared to Models 1 and 2 suggests these factors may be covariant, as shown by their correlation (0.62, $p \leq 0.01$).

Model 4 shows that relative to uneducated women, primary, lower secondary and secondary/higher education were associated with increments in height of 0.88 (0.46, 1.29) cm, 1.14 (0.64, 1.64) cm, and 1.56 (1.16, 1.97) cm respectively. Adjusting for these associations, the coefficients for early marriage and first pregnancy decreased, with first pregnancy not reaching statistical significance. Marrying at 10-14 years and 15 years were still independently associated with decrements in height of -0.58 (95% CI -1.07, -0.09) cm and -0.60 (95% CI -1.08, -0.12) cm respectively.

In summary, after adjusting for women's education, early marriage and first pregnancy < 16 years accounted, in combination, for a decrement of ~ 1.4 cm in height. This 1.4 cm decrease is derived by adding the effect of ~ 1.00 cm for early marriage and -0.42 cm for early pregnancy from Table 3, Model 3. **There were no multicollinearity issues given the low VIF values (< 1.6).**

For uneducated women only

Next, we restrict our sample to the uneducated women only ($N=5,054$), as their height is entirely independent of any benefits of attending school. **Table 4** shows the results were similar to the full sample, with the association of early first pregnancy on height (Model 2) appearing to work through early marriage, which was associated with shorter height (Model 3). Model 3 shows that for uneducated women, marrying < 16 years was associated with a -0.63 (95% CI -1.25, -0.01) cm decrement in height.

Table 4 near here***Adjusting for husbands' education and marital household asset score***

We next consider whether these associations might be explained by selection effects, in other words, through certain types of husbands selecting both younger and shorter wives. As hypothesised, **Table 2 showed** that poorer men, and less educated men, tended to marry women when they were younger and also tended to pair with shorter women. We therefore further adjust Model 4 from Table 3 for husbands' education level and marital household asset score (**Table 5**). **Table 5, Model 1** shows that independent of these husbands' traits, as well as women's education level, women's height remained significantly associated with both age at marriage and age at first pregnancy. Repeating this analysis among **only** the uneducated women reveals very similar findings (**Model 2**).

Table 5 near here

Table 5 Model 1 indicates that marrying at 10-14 years was associated with a decrement in height, of -0.56 (95% CI -1.05, -0.07) cm, and marrying at 15 years -0.60 (-1.07, -0.11) cm. First pregnancy <16 years was associated with a decrement in height of -0.41 (95% CI -0.83, 0.00) cm. In comparison to Table 3 Model 1, the coefficients for women's age at marriage and first pregnancy decreased slightly, and each was still independently associated with height, after adjusting for women's education, their husbands' education and marital household assets.

In **Model 2**, the final adjusted model for uneducated women only shows marrying at 10-14 years was associated with a decrement in height, of -0.58 (95% CI -1.19, -0.04, $p=0.068$) cm, and marrying at 15 years -0.66 (-1.28, -0.04) cm. First pregnancy <16 years was associated with a decrement in height of -0.47 (95% CI -0.95, 0.00, $p=0.051$) cm. In comparison to Table 4, Model 3, the coefficients for marrying at 15 years increased slightly, and marrying at 10-14 years and first pregnancy <16 years were no longer statistically significant.

In summary, for the full sample, marriage and first pregnancy <16 years accounted, in combination, for a decrement of ~1.0 cm in height after adjusting for education and marital assets. This 1.0 cm decrease is derived by adding the effect of ~-0.60 for early marriage and -0.41 for early pregnancy from Table 5, Model 1. For uneducated women only, marriage at 15 years and first pregnancy <16 years accounted, in combination, for a decrement of ~1.1 cm in height after adjusting for husbands' education and marital assets. This 1.1 cm decrease is derived by adding the effect of -0.66 for early marriage and -0.47 for early pregnancy from Table 5, Model 2. **There were no multicollinearity issues given the low VIF values (<1.7).**

Interactive associations of women's height with their age at marriage and first pregnancy, stratified by husbands' traits

Figure 1 shows 3D plots of women's height in association with either their age at marriage or their age at first pregnancy, stratified by husbands' education level or household assets. (Figures 1a-d). (Tabulated values are provided in Supplementary Table S2). **Overall, these plots help to visualise the difference between marrying early to an uneducated or poor man versus marrying later to an educated or wealthy man. They illustrate how both women's age at**

1
2
3 marriage and first pregnancy, and husbands' traits (e.g. education and wealth), are
4 independently associated with height.
5
6
7

8 **Figure 1 near here**
9

10
11 **Figure 1a** shows that on average, women who were married ≥ 18 years to a highly educated
12 man were over 3 cm taller than women who married < 15 years to an uneducated man. For any
13 level of husbands' education, later marriage was associated with taller height. However, the
14 slopes did not differ across the different groups, and the interaction term was not significant in
15 the linear regression model (i.e. the association of women's height with her age at marriage or
16 first pregnancy do not vary according to her husbands' traits). The same pattern of results was
17 apparent for the interactive association of women's height with their age at marriage and the
18 marital household asset score (**Figure 1b**), with their age at first pregnancy and their husbands'
19 education level (**Figure 1c**) and with their age at first pregnancy and the marital household
20 assets (**Figure 1d**).
21
22
23

24 **DISCUSSION**
25

26 This paper investigated the independent associations of women's early age at marriage and first
27 pregnancy with their height, in a cohort of women from rural lowland Nepal. We found that
28 shorter stature was independently associated with both early marriage and early pregnancy.
29 These two factors accounted for a decrement of 1.4 cm in height, which decreased to 1 cm after
30 adjusting for education and wealth.
31
32

33 Whilst adult height is considered a highly heritable trait (Fisher, 2019; Perkins et al., 2016;
34 Silventoinen et al., 2013), we found as hypothesised that broader bio-social factors also shape
35 women's height. Of particular interest, women's early age at marriage and first pregnancy were
36 independently associated with shorter height. Although our study could not test the potential
37 mechanisms explaining the association of early marriage and shorter height, previous research
38 suggests these may include: poverty and socio-cultural discrimination against women, which
39 may impact on their nutrition and growth (Bajracharya & Amin, 2012; Subramanian et al.,
40 2011); chronic under-nutrition during adolescence, especially during pubertal development
41 (Rah et al., 2008; Sear et al., 2004); and psychological distress related to early marriage
42 (Chorghade et al., 2006; Clarke et al., 2014; Harris-Fry et al., 2018). Some of these mechanisms
43 could account for why women are already both short and young when they marry, whereas
44 others could account for a constraint on growth after marriage. Puberty may also be associated
45 with marriage and first pregnancy age, although evidence on the timing of these events is
46 inconsistent (Chari et al., 2017; Raj et al., 2015; Wells, Cole, et al., 2019).
47
48
49

50 Beyond age at marriage, women who began reproduction at a young age also showed a small
51 decrement in height. A potential mechanism could be the competition for nutrients between
52 maternal and foetal development, as has been found in previous studies (Allal et al., 2004; Rah
53 et al., 2008; Sear et al., 2004). From the perspective of evolutionary life history theory,
54 maturation and growth may also be considered subject to a trade-off (McIntyre & Kacerosky,
55 2011; Wells, Ness, Sear, Johnstone, & Stearns, 2017). Women's reproductive fitness increases
56 in association with height, however this is counter-balanced by the cumulative risk of mortality
57 during the pre-reproductive period (Allal et al., 2004). The optimal time for ceasing to grow
58
59
60

1
2
3 and starting to reproduce is therefore expected to represent a compromise between these
4 variables, and it is then expected to vary in association with ecological conditions.
5

6
7 **Beyond trade-offs between growth and reproduction in women, maternal stress can also reduce**
8 **the energy available for investing in growth, maintenance or reproduction (Diagne et al., 2000;**
9 **Jasienska, 2009; Shukri et al., 2019). Indeed, consistent with work on younger age groups**
10 **(Widdowson, 1951), our findings suggest that psychosocial stress is a plausible mechanism**
11 **contributing to the association of early marriage with shorter height. However, shorter height**
12 **may also indicate an overall constraint on food consumption, and hence reduced availability of**
13 **energy for all life history functions.**
14

15
16 **Given that height growth in adolescence is potentially substantial, and may also allow recovery**
17 **from early growth faltering (Prentice et al., 2013), constraints on growth during this period**
18 **may propagate long-term adverse effects on women's health and their reproductive biology**
19 **(Kozuki et al., 2015), as well as survival and growth of the next generation (Özaltın et al.,**
20 **2010). Both psychological stress and malnutrition are associated with higher oxidative stress,**
21 **and both lower telomerase activity and shorter telomere length, which shape cell senescence**
22 **and longevity, thereby promoting earlier onset of age-related diseases (Epel et al., 2004).**
23 **Therefore, women who marry and reproduce early are not simply shorter and nor are they**
24 **healthy, because the process of 'becoming shorter' i.e. growth faltering, acts as a sign of a more**
25 **fundamental harmful process for health (Wells, Briend, et al., 2019).**
26
27

28
29 Social selection may contribute to these associations, and we attempted to illustrate these issues
30 using 3D plots. As expected, we found that men from households that had lower levels of
31 wealth, or who had low levels of education, tended to marry women who were both young
32 when they were married, and short. This indicates that part of the association between early
33 marriage and short height may be explained by **the** poverty of both spouses, and reflects factors
34 that influenced **their linear growth** before marriage. Consistent with this, we also found that
35 uneducated women also had short height and tended to marry early, **and these traits may reflect**
36 **their natal household's lower socio-economic status, or willingness to invest in building her**
37 **knowledge.** However, adjusting for these socio-economic variables, decrements in height were
38 still evident in association with both early marriage and early age at reproduction. **Our** 3D plots
39 **also** showed **independent** associations of height with age at marriage, or with age at first
40 pregnancy, **with** husbands' education or marital household wealth. **Therefore, while social**
41 **selection is certainly evident in our data, it does not fully explain the associations we detect,**
42 **rather the two mechanisms appear to be independent.**
43
44

45
46 **Women's education and the timing of their marriage are likely to be closely related (Marphatia**
47 **et al., 2020; Raj, McDougal, Silverman, & Rusch, 2014) and this relationship may be bi-**
48 **directional, although data on the timing of these decisions and events are usually not collected**
49 **(Sekine & Hodgkin, 2017; Wodon et al., 2017). Moreover, there was no confounding of**
50 **women's education in the analysis of uneducated women, and the similar magnitude of the**
51 **effect between the age variables and height of this group and the whole sample suggests the**
52 **association of education with height is independent. Potential pathways include educated**
53 **women being from wealthier and food-secure natal households, and experiencing better**
54 **nutrition and growth in early life.**
55
56

57
58 Following the rationale of the discipline of anthropometric history (Komlos, 1991, 1994;
59 Steckel, 1995), our study provides a new perspective on the lived experience of women in a
60

1
2
3 highly patriarchal society. Using height as an objective measure of health and living standards
4 is crucial in the context of our study, because traditional measures of women's empowerment
5 generally do not apply in this population (Gram et al., 2017). Collectively, women's shorter
6 stature, lower education and earlier marriage are markers of their lower social status in both
7 natal and marital homes. Whilst most studies of growth focus on infant nutrition and disease,
8 we focus on women's experience during adolescence, which is also a crucial period for growth
9 and maturity (Viner et al., 2015).
10
11

12 Although the magnitudes of effect that we describe in our study are relatively small, they
13 indicate energetic stresses that affect large numbers of women in this population, given that
14 37% of the population were married before 15 years and 20% had had their first pregnancy
15 before 16 years. Other studies have also linked shorter maternal height with poorer health and
16 lower human capital among both women and their offspring (Addo et al., 2013; Monden &
17 Smits, 2009; Murasko, 2020; Özaltın et al., 2010; Sear et al., 2004; Subramanian et al., 2011).
18 If the distribution of height is shifted downwards in the whole population only by 1 cm, the
19 absolute number of women pushed into a high-risk group of short stature may still be
20 substantial.
21
22

23
24 Strengths of our study include large sample size. We also had data on age at marriage, which
25 has not been collected in previous studies investigating associations between women's age at
26 first pregnancy and their height. Limitations include missing data, but these do not result in
27 bias. There may be potential error and recall bias due to women not knowing their exact age,
28 or having a birth certificate. Age-related variables were measured to the completed year, so
29 there was a loss of resolution over finely-grained results, but we can nevertheless detect
30 patterns robustly. We also lacked data on other factors that could potentially relate to women's
31 height such as their early growth patterns, age at menarche, and stressful life events; or their
32 natal household assets and living environments. Some of these factors might reflect their
33 mother's own nutritional or social status, and reproductive behaviour. Other limitations include
34 the lack of data on husbands' age and height, without which we cannot establish the social
35 aspects of short stature linked to early marriage relevant for both spouses. Data on these
36 processes may explain a greater proportion of the variance in our results, potentially decreasing
37 the magnitude of the effect of our explanatory variables. Our observational, cross-sectional
38 study can investigate the factors associated with women's height, but we cannot establish
39 causality.
40
41
42

43 **Conclusion**

44 We found that early marriage and pregnancy were each associated with women's shorter
45 height, and in combination accounted for a decrement of 1.4 cm, with this difference decreasing
46 to 1.0 cm after adjusting for husbands' and wife's education and marital household assets.
47 Although the magnitude of the association of exposures with maternal height in individuals
48 was small, these decrements indicate broader adverse effects on women's metabolism during
49 a sensitive period of development.

Figure legends

Figure 1. 3D plots of interactive associations of women's height with their (a) husbands' education and women's age at marriage, (b) marital household asset score and women's age at marriage, (c) husbands' education and women's age at first pregnancy and (d) marital household's asset score and women's age at first pregnancy.

Independent associations of women's age at marriage and first pregnancy with their height in rural lowland Nepal

Revised Tables

Table 1. Descriptive statistics

Dependent (outcome variable)	Women aged 20-30 years (N=7,146)	
	Mean	SD
Women's height (cm)	150.4	5.4
	Median	IQR
Marital household asset score	-0.41	2.4
Independent (predictor variables)	Frequency	%
Women's marriage age (y)		
10-14 years	2,664	37.3
15 years	1,769	24.8
16 years	918	12.8
17 years	904	12.7
≥18 years	891	12.5
Women's age at first pregnancy (y)		
<16 years	1,407	19.7
16-17 years	2,328	32.6
≥18 years	3,411	47.7
Women's education level (y)		
None	5,054	70.7
Primary (1-5y)	752	10.5
Lower secondary (6-8y)	494	6.9
Secondary or higher (≥9y)	846	11.8
Husbands' education level (y)		
None	3,625	50.7
Primary (1-5y)	923	12.9
Lower secondary (6-8y)	1,024	14.3
Secondary or higher (≥9y)	1,574	22.0

SD, standard deviation. **IQR Interquartile Range.**

Table 2. Mean values, women's height, age at marriage and first pregnancy by their education

Women's education (y)	<i>n</i>	Women's height (cm) (N=7,146)		Women's age at marriage (y) (N=7,146)		Women's age at first pregnancy (y) (N=7,146)	
		Mean	SE	Mean	SE	Mean	SE
None	5,054	150.0	0.08	15.0	0.03	17.5	0.04
1-5 years	752	151.0	0.18	15.3	0.07	17.7	0.09
6-8 years	494	151.3	0.23	15.6	0.08	17.7	0.10
≥9 years	846	151.9	0.18	16.7	0.07	18.7	0.08
<i>p</i> for trend		<0.001		<0.001		<0.001

<i>p</i> for trend		<0.001		<0.001		<0.001	

N, number; SE, standard error.

Table 3. OLS Linear Regression of the association of women's height with their age at marriage and first pregnancy and their education

	Model 1: Early marriage (N=7,146) (Adjusted R ² =0.005)	Model 2: Early pregnancy (N=7,146) (Adjusted R ² =0.003)	Model 3: Early marriage and pregnancy (N=7,146) (Adjusted R ² =0.006)	Model 4: Early marriage and pregnancy, women's education (N=7,146) (Adjusted R ² =0.017)
	β (95% CI)	β (95% CI)	β (95% CI)	β (95% CI)
	p-value	p-value	p-value	p-value
Women's marriage age (y): $\geq 18y$	Reference		Reference	Reference
10-14 years	-1.20 (-1.61, -0.79)		-0.99 (-1.48, -0.51)	-0.58 (-1.07, -0.09)
15 years	-0.97 (-1.41, -0.54)		-0.92 (-1.40, -0.44)	-0.60 (-1.08, -0.12)
16 years	-0.50 (-1.00, 0.00)		-0.49 (-1.01, 0.03)	-0.24 (-0.76, 0.28)
17 years	-0.49 (-0.99, 0.00)		-0.49 (-0.99, 0.01)	-0.38 (-0.84, 0.16)
Women's age at first pregnancy (y): $\geq 18y$		Reference	Reference	Reference
<16 years		-0.87 (-1.21, -0.53)	-0.42 (-0.84, 0.00)	-0.38 (-0.80, 0.04)
16-17 years		-0.34 (-0.62, -0.05)	-0.03 (-0.35, 0.30)	-0.06 (-0.39, 0.26)
Women's education (y): uneducated				Reference
1-5 years				0.88 (0.46, 1.29)
6-8 years				1.14 (0.64, 1.64)
≥ 9 years				1.56 (1.16, 1.97)
Constant	0.83 (0.48, 1.19)	0.30 (0.12, 0.48)	0.83 (0.48, 1.19)	0.19 (-0.19, 0.58)

N, number. CI Confidence Interval. β (95% CI) are height differences in cm. Women's height has been standardized for their age by taking the residuals from a regression of height as the dependent variable against age as the independent variable.

Table 4. OLS Linear Regression, association of uneducated women's height with their age at marriage and first pregnancy

	Model 1: Early marriage (N=5,054) (Adjusted R²=0.002)		Model 2: Early pregnancy (N=5,054) (Adjusted R²=0.002)		Model 3: Early marriage and pregnancy (N=5,054) (Adjusted R²=0.002)	
	β (95% CI)	p- value	β (95% CI)	p- value	β (95% CI)	p- value
Women's marriage age (y): $\geq 18y$	Reference				Reference	
10-14 years	-0.78 (-1.32, -0.24)	0.005			-0.54 (-1.16, 0.07)	0.085
15 years	-0.71 (-1.29, -0.13)	0.016			-0.63 (-1.25, -0.01)	0.046
16 years	-0.19 (-0.85, 0.46)	0.559			-0.16 (-0.84, 0.51)	0.635
17 years	-0.27 (-0.93, 0.40)	0.432			-0.26 (-0.93, 0.41)	0.445
Women's age at first pregnancy(y): $\geq 18y$			Reference		Reference	
<16 years			-0.67 (-1.05, -0.28)	0.001	-0.44 (-0.92, 0.03)	0.069
16-17 years			-0.24 (-0.59, 0.10)	0.165	-0.07 (-0.46, 0.32)	0.734
Constant	0.18 (-0.31, 0.68)	0.460	-0.14 (-0.37, 0.08)	0.212	0.18 (-0.31, 0.68)	0.460

N, number. CI Confidence Interval. β (95% CI) are height differences in cm. Women's height has been standardized for their age by taking the residuals from a regression of height as the dependent variable against age as the independent variable.

Table 5. OLS Linear Regression of the association of women's height with their age at marriage and first pregnancy, adjusting for husbands' education and marital household assets

	Model 1: All women (N=7,146) (Adjusted R ² =0.024)		Model 2: Only uneducated women (N=5,054) (Adjusted R ² =0.013)	
	β (95% CI)	p-value	β (95% CI)	p-value
Women's marriage age (y): $\geq 18y$	Reference		Reference	
10-14 years	-0.56 (-1.05, -0.07)	0.025	-0.58 (-1.19, 0.04)	0.068
15 years	-0.60 (-1.07, -0.11)	0.016	-0.66 (-1.28, -0.04)	0.036
16 years	-0.25 (-0.78, 0.27)	0.338	0.22 (-0.90, 0.45)	0.514
17 years	-0.36 (-0.86, 0.14)	0.162	-0.30 (-0.97, 0.36)	0.374
Women's age at first pregnancy (y): $\geq 18y$	Reference		Reference	
<16 years	-0.41 (-0.83, 0.00)	0.050	-0.47 (-0.95, 0.00)	0.051
16-17 years	-0.08 (-0.40, 0.24)	0.623	-0.07 (-0.46, 0.31)	0.703
