Exploring the nexus of urban form, transport, environment and health in large-scale urban studies: a state-of-the-art scoping review

Abstract

Background: As the world becomes increasingly urbanised, there is recognition that public and planetary health relies upon a ubiquitous transition to sustainable cities. Disentanglement of the complex pathways of urban design, environmental exposures, and health, and the magnitude of these associations, remains a challenge. A state-of-the-art account of large-scale urban health studies is required to shape future research priorities and equity- and evidence-informed policies.

Objectives: The purpose of this review was to synthesise evidence from large-scale urban studies focused on the interaction between urban form, transport, environmental exposures, and health. This review sought to determine common methodologies applied, limitations, and future opportunities for improved research practice.

Methods: Based on a literature search, 2958 articles were reviewed that covered three themes of: urban form; urban environmental health; and urban indicators. Studies were prioritised for inclusion that analysed at least 90 cities to ensure broad geographic representation and generalisability. Of the initially identified studies, following expert consultation and exclusion criteria, 66 were included.

Results: The complexity of the urban ecosystem on health was evidenced from the context dependent effects of urban form variables on environmental exposures and health. Compact city designs were generally advantageous for reducing harmful environmental exposure and promoting health, with some exceptions. Methodological heterogeneity was indicative of key urban research challenges; notable limitations included exposure and health data at varied spatial scales and resolutions, limited availability of local-level sociodemographic data, and the lack of consensus on robust methodologies that encompass best research practice.

Conclusion: Future urban environmental health research for evidence-informed urban planning and policies requires a multi-faceted approach. Advances in geospatial and AI-driven techniques and urban indicators offer promising developments; however, there remains a wider call for increased data availability at local-levels, transparent and robust methodologies of large-scale urban studies, and greater exploration of urban health vulnerabilities and inequities.

1. Introduction

Currently, almost 60% of the global population (~4.8 billion people) live in the urban environment and by 2050 nearly seven out of ten people will inhabit cities 1,2. There are a host of reasons attributed to the rising trend of migration and urbanisation; mainly, cities provide rich opportunities for education, employment, wealth, and innovation 3,4. Yet cities can also be a concentrated source of environmental exposure stressors (e.g., air pollution, noise, and heat) 5,6,7, perpetuate unhealthy lifestyles 8, and exacerbate health inequities 9. Concurrent with rapid urbanisation, climate change poses an additional threat to urban health and sustainability challenges 10,11. Cities account for 75% of the world's energy-related greenhouse gas emissions 12 and can be a major contributor to biodiversity loss 13. Although viewed as the principal drivers of climate change, cities also offer a large part of the solution 14,15. In Europe, initiatives that aim to reduce greenhouse gas emissions and achieve carbon neutrality include the EU's Green Deal 16 and the Paris Climate Agreement 17. These initiatives recognise the pivotal role of sustainable and liveable cities for achieving these objectives, which in turn will protect public and planetary health.

The pathways of urban form, environmental exposures, and health are intricate, and the magnitude of these associations have not been widely substantiated¹⁸. Although cities are a complex system, a conceptual framework developed by Nieuwenhuijsen & Khreis¹⁹ (Figure 1) illustrates the multitude of urban and transport planning pathways that contributes toward the health of urban populations. Urban form denotes the structure, design, and physical features of an urban environment²⁰, captured by the urban design pillar in Figure 1. There are two dominant urban forms; the first, known as compact cities, is characterised by dense housing and road infrastructure, and the second by dispersed low density infrastructure with high sprawl^{8,21}. Both are notionally inconducive to health and sustainability, as the first lends itself to increased pollutant emissions and noise levels, accentuated hot temperatures, and reduced green space⁸; whilst the second favours motorised traffic and motor vehicle dependency, poorer public transportation infrastructure, lower social cohesion, and reduced physical activity levels^{4,22}. However, the compact city model has the conceptual benefits of shorter commuting distances that promote active mobility and increase social cohesion, which highlights the potential trade-offs and complexity of urban design²³. Naturally, cities can be a combination of these forms.

The health burden attributable to environmental exposures in urban settings is well documented 7,8,24 . In 2019, particulate matter diameter $2.5\mu m$ (PM_{2.5}) and ozone air pollution were estimated to cause 4.51 million premature deaths worldwide 25 , and road traffic injuries were

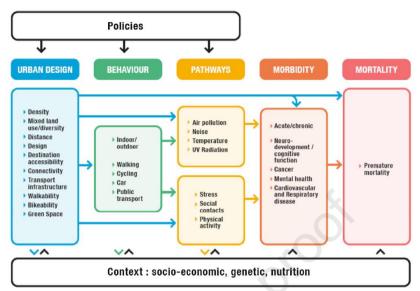

Figure 1 Conceptual framework of the links and pathways between urban design, environmental exposures and health ¹⁹.

ranked the leading cause of disability-adjusted life years (DALYs) for ages 10-49 years, ranking 10th for ages 50-74 years²⁶. Trends of increasing heat-related morbidity and mortality are largely ascribed to climate change²⁷ and are exacerbated in urban environments due to the urban heat island (UHI) effect, an occurrence wherein urban areas exhibit elevated temperatures compared to their rural surroundings²⁸. In addition to premature mortality, heat-related impacts include increased mental health distress²⁹, cardiorespiratory-mortality³⁰, and hospital admissions³¹. Although a lesser studied environmental risk factor, chronic exposure to noise pollution can also have adverse health effects; at least 20% of the European urban population is likely to be exposed to noise levels harmful to health³². In 2017, 18 million people in Europe were estimated to experience high annoyance from noise and 5 million sleep disturbance. Sedentary behaviour and reduced physical activity are well established risk factors of health burden and are often more prevalent in urban environments owing to lifestyles and built environment characteristics²². Perhaps the starkest of adverse impacts from sedentary behaviour³³, sitting for 10 hours a day is associated with 48% increased risk of all-cause mortality compared to 7.5 hours a day³⁴.

Translating health burden statistics into actionable recommendations for policy requires research to effectively discern the intricate relation between urban form, environmental stressors, and health. However, uncovering causal inferences is complex due to the multiple pathways, long causal chains, and dynamic nature of contextual factors (e.g., neighbourhood attributes) and compositional (e.g., demographic characteristics)³⁵, alongside the multidisciplinary nature of

urban and transport planning related impacts. Health impact assessment (HIA) is a widely adopted decision support tool that aids evidence-informed policies. HIAs are valuable within urban health research as the impacts of urban planning on health determinants and scenarios can be modelled and estimated impacts often have high comprehensibility to decision-makers, which helps generate awareness^{36,37}. Temporal HIAs offer the additional advantage that predicted impacts reflect the historical trajectory of exposures and health burden, and thus, changes in exposure, impacts, and policies can be tracked over time³⁸. To effectively interpret the accuracy of forecasted impacts and the existing evidence base necessitates understanding the uncertainties inherent in model assumptions and how these vary across studies³⁸. Moreover, qualitative data, such as societal preferences, are integral in elucidating the constituents of an urban ecosystem. The Neighbourhood Environment Walkability Scale (NEWS) is one such tool designed to gather perceptions of neighbourhood attributes linked to physical activity (e.g., street connectivity)³⁹. The widespread adoption of NEWS underscores the need for comprehensive, proxy tools that assess city liveability⁴⁰. However there exists a plethora of different, context-specific walkability indices^{41,42,43,44}; this underscores the resultant limitations in comparing studies that employ diverse methodologies, and the challenge in obtaining universally applicable insights into urban environmental health pathways and attributable impacts.

Large-scale urban studies offer generalisable and robust evidence for elucidating the nexus among city form, climate, transport, and environmental and health impacts. However, to the best of knowledge, there is no scoping review that synthesises evidence from large-scale urban studies that investigate these interconnections. Exploration of commonly employed methodologies, associated limitations, and key research gaps can highlight future research opportunities.

As such, the purpose of this scoping review was two-fold:

- 1) Synthesise evidence from large-scale urban studies that focused on the relation between urban structures, transport, environmental exposures, and health.
- 2) Advanced understanding of current knowledge and gaps, methodologies applied, limitations, and opportunities for the improvement of current research practice.

The research questions we sought to address were:

- 1) What methodologies were applied in urban form, transport and mobility, and urban environmental health studies from 2003 to 2023?
- 2) What are novel methods and indicators within urban environmental health research?
- 3) What knowledge gaps necessitate further exploration?

2. Methods

This review was conducted as part of The Urban Burden of Disease Estimation for Policy Making proiect (UBDPolicy). UBDPolicy aims to improve the estimation of health impacts and socioeconomic costs, or benefits, of environmental determinants in almost 1000 European cities in 31 countries⁴⁵. Through provision of estimates of health impacts from air pollution⁵, noise⁶, heat⁴⁶, and green space⁴⁷ in regular three-yearly reporting intervals, UBDPolicy aims to advance understanding of wider impacts and trends from urban planning across Europe and build healthy and sustainable urban scenarios for specific case studies. Therefore, the conclusions drawn from this review and their applicability for UBDPolicy shaped the reasoning behind the methods employed. Given the exploratory nature required to meet the review's objectives, we conducted a scoping review suited to identifying knowledge gaps and emerging methods within a broad topic area⁴⁸. The anticipated heterogeneity of study designs of reviewed articles and practical and resource constraints rendered a systematic review or meta-analysis less suitable. Further, a UBDPolicy workshop held in Sitges, Spain, in October 2023 allowed expert consultation for identification of additional applicable studies. A literature search was performed using the bibliographical database PubMed. Figure 2 provides a visual representation of the process of article inclusion and exclusion.

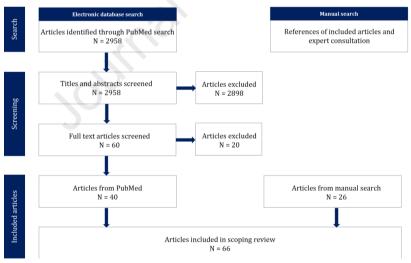

Figure 2 Flowchart of the literature search inclusion and exclusion process

2.1 Keywords search process

Seven independent searches using PubMed were carried out (Table 1). The same search terms to describe urban form were included in the seven searches. The first search focused on urban form and health, the second on urban environmental health, and the third on urban indicators. The distinction between urban form and urban environmental health pertains to the former

investigating the direct link between urban form and health whereas for the latter, studies consider the exposure pathway either by assessment of urban form to environmental exposures or exposures to health.

For the second category of urban environmental health studies, five searches encompassed the following key themes: air pollution and health impacts; temperature and health impacts; green space and health impacts; noise and health impacts; and transport and mobility. The searches returned 2958 unique articles (Figure 2). Article abstracts were screened for relevance based on the inclusion criteria and objectives of UBDPolicy, which resulted in 40 papers for inclusion. An additional 26 papers were obtained from a manual search conducted by scanning reference lists for relevant studies and from expert consultation. This resulted in nine urban form and health studies 45 urban environmental health studies, and 12 urban indicator papers. A total of 66 studies were included. Table 1 provides a summary of the search terms used and results of each search. Figure 3 categorises articles by theme and year of publication.

 Table 1

The same search terms relating to "urban form" were included in all searches. ^a Values denote the total number of articles obtained from the respective search terms, for each search performed. ^b Values denote the number of relevant articles included from PubMed search, following exclusion. Exclusion was based upon studies analysing < 90 cities, or not specifically assessing health impacts. The exclusion criteria did not apply to articles focused on indicators. ^c Values denote the total number of included articles, by theme, after a supplementary search using included article reference lists and from expert consultation.

2.2 Inclusion criteria

Article inclusion criteria and conducted searches were divided into three search categories; urban form and health, urban environmental health (subdivided into HIA studies and other research methodologies), and urban indicators. For the second search category, a distinction of HIA methodologies was made to allow for effective exploration

of methodologies and affiliated challenges Figure 3 Number of articles by published year and theme.

within the broader urban environmental health field. The inclusion criteria for search categories one and two (urban form and health and urban environmental health studies) constituted studies were required to have analysed at least 90 cities, be written in English, and published in peer-reviewed journals from January 2003 to December 2023. The inclusion criterion was set at 90 or more cities as this number was considered appropriate to standardise data collection across different environmental and climatic gradients and to be representative of studies with less than 90 cities. Studies published from January 2003 to December 2023 were included to ensure methodologies and findings were reflective of current levels of urbanisation and health impacts. For the second search category of urban environmental health studies, the environmental

exposures included were: air pollution; temperature; green space; road traffic noise; and transport and mobility.

The third search category focused on urban indicators. Indicators and frameworks considered relevant were those that focused on urban design and environmental health. The inclusion criteria specified studies should be written in English and published in peer-reviewed journals from January 2003 to December 2023.

2.3 Exclusion criteria

The exclusion criteria applied to both searches encompassed environmental exposures not relevant to UBDPolicy (such as infectious diseases), studies that did not evaluate health impacts, health outcomes considered less attributable to city design and planning, and studies published before January 2003. For the third search category of urban indicators, the exclusion criterion of studies analysing less than 90 cities did not apply, as indicators can be scaled and applied to different contexts.

3. Results

Of the 66 studies included in this review, the geographical regions covered were: Global (24), China (14), Europe (13), Latin America (9), the United States (3), and Africa (3) (Figure 4 and Table 2). While studies specific to South-Asia, South-East Asia, and the Middle East were not considered in this review, a number of cities from these regions featured in the global studies. A total of 45 studies examined urban environmental exposures and health, with the

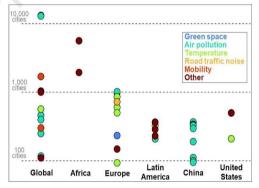

Figure 4 Number of cities analysed in each study, categorised by region and environmental exposure.

majority (29, \sim 64%) assessing air pollution health impacts. The least studied exposure was road traffic noise (1, \sim 1.5%). The number of cities analysed spanned a wide range (93 - 13,189 cities), with variation in city definitions employed (Tables 3 and 4). All studies conducted in China examined the health effects from air pollution exposure, whereas less studied regions, such as Africa were amongst the largest in scale in terms of the number of cities analysed (Figure 4). Examination of findings is in accordance with the thematic order outlined in Table 2, and constitutes four sections: urban form and health, urban environmental health, HIAs, and urban indicators.

Table 2 Summary of 66 included studies, by theme, geographic scope, and number of cities analysed.

3.1 Urban form and health

Many studies that assessed urban form employed urban form metrics at city-level, namely: population density^{49,50,51,52}, fragmentation^{53,50}, sprawl²¹, built-up area^{53,21}, compact development⁵⁴, intersection density⁵³, and mass transit infrastructure^{49,53}. Fewer studies explored spatial observations and patterns within-city level^{52,54,55}.

Health outcomes included long-term and short-term outcomes; long-term outcomes encompassed non-communicable diseases, cancer-related mortality, infant mortality, and mental distress, whilst short-term outcomes were violence-related and unintentional injury-related mortality (Table 3). The only urban form studies to include social and demographic variables in analyses were conducted in Latin America and employed the social environment index, which comprises area-level measures of education attainment, access to water and sewage facilities, and

overcrowding^{50,53}. Higher values indicate more favourable social conditions and a higher quality of life.

Findings suggest that lower city fragmentation, high population density, high connectivity, and higher rates of public transportation have positive impacts on health and reducing premature mortality^{49,53,55,56}. Car-centric urban planning⁵⁵ was reported to have adverse effects on health, whilst in Africa greater sprawling cities were shown to have higher energy demands⁵². City size was identified as the most critical variable for influencing urban sprawl with round and compact city designs generally more advantageous⁵². Another African-based study conducted spatial analysis of four urban form variables in an effort to classify cities based on urbanisation dynamics⁵¹. Prieto-Curiel et al. developed a systematic approach to capture and delineate the spatial interactions between variables of city size, market potential, level of urbanisation, and local dominance; the latter indicates city size in relation to adjacent agglomerations⁵¹. Results showed diverse and distinct interactions of spatial variables, finding this to impact the rate of urban growth, the emergence of new agglomerations, and the clustering of cities. In another classification study, Taubenböck et al. utilised remote sensing and cluster analysis to classify 1500 cities worldwide into seven distinct types⁵⁴. Findings highlighted the issue of spatialmorphological inequality, where the shape of cities was shown to be critical in shaping functional and social aspects of urban living, and 30% of sparsely built areas were found to accommodate 10% of the total population. Illustrating the complexity of urban form, a global study spanning 24 years found sprawl to strongly correlate with human development index (HDI), which comprises life expectancy, educational attainment, and standard of living (measured by gross national income (GNI) per capita); cities characterised by extensive urban sprawl exhibited high values of HDI21. Between 1990 and 2014, Europe was identified as the continent with the highest degree of urban sprawl and had the highest sprawl rate, increasing by 51% since 1990²¹.

3.2 Urban environmental health

Urban studies that investigated the exposure pathway to health in general followed an ecological (10, \sim 15%) or cross-sectional study design (6, \sim 9%), with a minority encompassing modelling studies (2, \sim 3%), or meta-analysis (1, \sim 1.5%) (Table 3). Certain studies adjusted for population demographic characteristics in their analyses, such as household income⁵⁷, income inequality⁵⁸, self-rated health⁵⁵, educational attainment⁴⁹, and race and ethnicity⁵⁷. Seven studies (\sim 11%) directly examined the modification effect of socioeconomic status (SES) on the association between the urban environment and health, applying gross-domestic product (GDP) per capita^{59,60,61}, GINI coefficient^{58,61}, or GNI per capita⁶². In all studies that performed stratified

analyses of socioeconomic (SE) and demographics variables, aggregate data were applied at city-level.

3.2.1 Urban form and air pollution

Studies consistently reported significant proportions of urban populations to be exposed to ambient pollution that exceeded WHO $2005^{10,59,63,64}$ and $2021^{60,65}$ guidelines. Findings from Latin America showed 85% of the study population exposed to ambient nitrogen dioxide (NO₂) concentrations and 58% exposed to PM_{2.5} levels that exceeded WHO guidelines^{59,60}. Whilst Anderson et al. reported all the 5625 African cities under study failed to meet WHO 2005 clean air guidelines¹⁰.

The relation between city size, higher population density, and pollutant concentrations was somewhat inconsistent. A Latin American study reported larger population size was associated with higher annual mean PM_{2.5}, whilst higher population density was positively associated with lower levels of PM_{2.5} in a separate univariate model⁵⁹. Another Latin American study reported denser and more congested cities to have higher NO₂ and PM_{2.5} concentrations, owing to higher motorisation rates and congestion⁶⁰. The same study reported highest variability in NO₂ population exposure was within cities and an increase in green space at neighbourhood level, rather than city-level, was associated with lower local levels of NO₂⁶⁰. Interestingly, Rezaei & Millard-Ball observed cities with greater density exhibited reduced per capita PM_{2.5} transportation emissions; however, increased exposure was noted due to the population residing in closer proximity to emission sources⁶². Authors noted greater variation in emission exposure between income groups, as opposed to urban form metrics and income where no significant correlations were found. Another study found higher city GDP per capita and higher intersection density correlated with elevated levels of PM_{2.5}⁵⁹. The only study to include educational attainment in analyses found population groups of higher educational attainment were exposed to higher NO₂ concentrations⁶⁰.

3.2.2 Urban form and temperature

Studies that assessed the relationship between urban form, temperature, and health mainly focused on the impact of non-optimal temperatures on premature and cardiovascular-related mortality^{58,66,67}. In Europe, lower minimum mortality temperature (MMT) positively correlated with lower GDP per capita; for example, spatially close cities of Austria (Vienna) and Slovakia (Bratislava) exhibited MMTs of 20.5°C and 18.4°C and GDP per capita of 29,301 and 11,348, respectively⁶¹. A Latin American study found the GINI coefficient, indicative of income inequality, was the sole modifier that showed a statistically significant association with all-age MMT⁵⁸. Cities

exhibiting the highest income inequality experienced a mortality rate 3.45% higher than those in the lowest tertile of income inequality⁵⁸. For ages 65 years and older, increased levels of poverty and residential segregation were linked to higher cold MMT⁵⁸. Of note, there were higher deaths associated with cold, 5.09% out of 5.75% non-optimal temperature attributable deaths at all ages, compared to 0.67% deaths associated with heat⁵⁸. Zhou et al. found city size and compactness to have the strongest influence on UHI intensities, concluding small to medium sized cities were most effective in alleviating UHI⁶⁸.

3.2.3 Urban form and green space

Generally, studies found the health benefits of urban green space to depend upon the distribution within a city^{57,62,69}. Reported health benefits included lower levels of obesity^{57,69}, mental health disorders⁵⁷, and lower pollutant levels^{10,67}. Across African cities, linear econometric models predicted the impact of increasing green space cover by at least 25% and found this would reduce $PM_{2.5}$ to moderately safe levels (12 - 35.4 μ g/m³)¹⁰. Evidence varied on whether the type of green space had an effect on benefits. Olsen et al. explored a range of land uses and the impacts at individual and aggregate city-level across European cities and found relatively wild green space (constituting agricultural, wetlands, and semi-natural areas) was associated with lower standardised mortality rate⁷⁰. Another study found a significant correlation between poor mental health and greenness and between obesity and tree cover, reporting no significant relationships between greenness and obesity, or between tree cover and mental health⁵⁷. A notable strength of Browning et al.'s study was the inclusion of moderation tests for exploring effect modification, analysing sociodemographic variables and urban sprawl (defined by population density, the percentage who drive to work, and residential density). When adjusting for spatial and confounding variables, population density (-0.15, -0.17), physical inactivity (0.65, 0.67), median age (-0.11, -0.11), and income (-0.98, -0.95) were significantly associated with obesity (reported β coefficients are for greenness and tree cover, respectively). Whilst median income (-0.85, -0.86) and physical inactivity (0.21, 0.2) were significantly associated with poor mental health⁵⁷.

Although evidence was mixed, urban form characteristics of denser housing⁷⁰, higher population density⁷¹, and more compact cities¹⁰ generally showed a negative association with green space availability. Aiming to advance predictions of the benefits of increasing green space, Marando et al. developed a model that simulated the microclimate regulation of urban green infrastructure across European cities⁷². To lower temperatures by 1°C in urban areas, a minimum tree cover of 16% was required. Of the Functional Urban Areas (FUAs) studied in Europe, 32% (192 FUAs) had tree cover below 16%. A global review by McDonald et al. explored how urban areas can achieve both population density and green space and found a 10% increase in density was associated with

2.9% decline in tree cover⁷². Interestingly, the reported negative correlation was weakest when explored at neighbourhood level compared to city-level, suggesting some neighbourhoods achieved more tree canopy than was expected based on population density. Supportive findings by Anderson et al. observed variation between cities in the magnitude of cooling benefits from green space and attributed this to different distributions of green space within cities ¹⁰. Cities with the same availability of green space (20%) but different levels of proximity experienced varying cooling effects during a heat wave, 55% of one city's population was estimated to benefit in contrast to 16% of another city's population ¹⁰.

3.2.4 Urban form and transport and mobility

Bassolas et al. developed a metric that quantifies the hierarchical organisation of urban mobility, considered a proxy for urban inhabitants' needs being met⁷³ (Table A1 in Appendix). Weekly trip flow information of 300 million people in 301 global cities was aggregated into weighted networks to identify hotspots of activity at spatial resolution of ~1.27km² and city-level. The varied spatial distribution patterns of hotspots captured differences in city organisation, permitting inferences of the effects of urban structure on transportation (mode share), pollutant emissions, and health outcomes (ischaemic stroke mortality and fatal traffic injuries). Greater urban mobility was attributed to more population mixing (Pearson's coefficient ($R^{2}P$) = 0.21, Spearman's coefficient $(R^2_s) = 0.24$), extensive use of public transportation $(R^2_P = 0.45, R^2_S = 0.39)$, higher levels of walkability ($R^{2}_{P} = 0.47$, $R^{2}_{S} = 0.58$), and better health outcomes (ischaemic stroke mortality rate per 100,000 inhabitants: $R^2P = 0.31$, $R^2S = 0.26$, fatal traffic injuries: $R^2P = 0.34$ and $R^2S = 0.33$). Another study that applied advanced techniques of remote sensing and global geospatial data identified nine global city types by modularity analysis⁷⁴. The poorest performing cities for road traffic injuries were characterised by sparse and irregular shapes with large blocks, whereas the best performing city types were characterised by high rates of public transportation. Road traffic injury burden of 9.6 million DALYs were attributed to suboptimal urban design⁷⁴.

	Browning et al., 2018 ⁵⁷	United States (496)	Cross- sectional		500 Cities project ¹¹⁰	Obesity Mental health	500 Cities project ¹¹⁰	NDVI Tree cover	Multi- Resolution Land Characteristics Consortium ¹¹²			Spatial moving average models

						Main findings
						 Greener cities had less obesity and better mental health outcomes. No evidence that tree cover was more strongly linked to positive health outcomes compared to greenness. Cities with lower median household income had greater benefits from green space compared to wealthier cities. Sprawl did not have a moderating effect on the greenspace-health link. Regardless of a city's population density, tree cover was linked to better obesity outcomes and overall greenness was linked to better mental health outcomes.
	Anderson et al,, 2022 ¹⁰	Africa (5625)	Modelling	Continuously built- up area with <200m between two buildings and	Africapolis ⁷⁵	Urban green space fraction Proximity to green WorldClim; Urban form Space Agency's Linear econometric space GHSL14 metrics World Cover models PM25
				≥10,000 inhabitants		• None of the cities under study met the WHO 2005 recommended air quality levels. • If cities had at least 25% green space cover PM ₂₅ levels could reach moderately safe levels. • The benefits of green space availability were not the same as proximity to green space. Recommendations included varied-sized patches of green throughout the city.
						All-cause mortality Richardson et . Land cover uses' supplementary Linear regression models (SMR) al., 2017117 .
	Olsen et al., 2019 ⁷⁰	Europe (233)	Cross- sectional	Large Urban Zones of ≥100,000	Urban Atlas 2018116	Main findings
				inhabitants		 No evidence that the distribution of mixed land use was related to mortality rates. The proportion of specific land use within a city was related to SMR. Higher proportion of natural spaces, and less dense or non-residential land use was associated with lower mortality. Relatively 'wild' green spaces (e.g., forest, wetlands, semi-natural areas) were associated with lower SMRs; this association was observed across sexes. Dense housing was related to higher SMR, and was most prominently seen in Western European cities.

^a Statistical method for estimation of association between urban form, exposures, and health.

» BASE model: mean distance between buildings is a functional relation to the number of Buildings and their average Area and the Sprawl and the Elongation of its spatial arrangement. Allows relation of city morphology to distance indicators (e.g., sprawl, elongation, and polycentricity) and the energy demand from transport.

-Cold waves defined as two, three, or at least four consecutive days with daily temperature lower than the 5th percentile of temperatures recorded in each city.

a Variables included in cooling index: tree cover density, water evaporation from tree canopies, vaporisation of intercepted rainfall from vegetation.

Urban form metrics include sprawi, city elongation, built-up intensity, intersection density, average node degree, city centre building density, types of green cover, total footprint centre 1km, is pyramid, urban green space.

Land covers/uses include agriculture, semi-natural areas, wetlands, green urban areas, industrial, commercial, public, military, discontinuous low density urban fabric, residential, isolated structures.

3.3 Health impact assessment

Of the 45 urban environmental health studies, 25 applied a HIA methodology. All the HIAs followed a comparative risk assessment (CRA) approach, with all but one HIA¹²¹ assessing the potential health impacts under an alternative scenario (i.e., counterfactual)³⁸. To effectively examine the different HIA methodologies employed, this section is structured as follows: environmental exposures, population and health data, exposure response functions (ERFs) and counterfactual scenarios, and summary of findings.

3.3.1 Environmental exposures

Almost 85% of the HIAs (21) analysed the health impacts from air pollution. Of these HIAs, eight obtained pollution exposure data from the common data repository of China National Environmental Monitoring Centre¹²², two utilised a dataset produced by Anenberg et al.¹²³, and the remainder obtained estimates from emission inventories^{124,125,126,127,128,129,130} or from air pollution models (e.g., land use regression models, EMEP MSC-W chemical transport model, and SHERPA tool)^{5,131,132,133} (Table 4). The majority of HIAs that focused on air pollution analysed PM_{2.5} as the environmental exposure (14, ~56%), followed by ozone (8, ~32%), NO₂ (7, 28%) and particulate matter diameter $10\mu m$ (PM₁₀) (2, 8%) with one study assessing carbon dioxide (CO₂)¹³¹ and one sulphur dioxide (SO₂) and total suspended particles (TSP)¹³⁴. Of the 25 HIAs, eight (32%) assessed temporal trends in air pollution, the longest trend assessed global NO₂-attributable paediatric asthma incidence across 29 years¹²³.

Of the four HIAs that analysed alternative environmental exposures, two assessed temperature health impacts^{48,135}, obtaining temperature records from ERA5-Land dataset $(100\text{m}^2)^{48}$ and Copernicus UrbClim model application $(100\text{m}^2)^{135}$; one assessed green space⁴⁹ by normalised differential vegetation index (NDVI) and percentage of green area (%GA), obtained from the US Geological Survey⁸⁹ and European Urban Atlas¹³⁶ (250m²); and one estimated the impact of road traffic noise⁶. Of the strategic noise maps acquired from the Environmental Noise Directive and local sources ~83% were considered low or moderate quality. Masselot et al. was the only HIA to analyse both extreme heat and extreme cold¹¹⁵.

3.3.2 Population and health data

Similar city population data sources were applied based on the country HIAs were conducted in. For HIAs conducted in China, the National Bureau of Statistics of China was a common population data depository; all HIAs conducted in Europe (6, 24%) utilised the Urban Audit, whilst Global HIAs obtained population estimates from European Commission's Joint Research Centre or the Centre for International Earth Science Information Network (CIESIN) (Table 4). Health data were

generally obtained at national or provincial-level and applied to city-level; two HIAs in China^{128,134} and all HIAs conducted in Europe utilised city-level health data.

A diverse range of health outcomes were analysed, with each HIA examining between one and 24 health outcomes (Table 4). Mortality outcomes were a key focus, encompassing categories of all-cause mortality (14, 56%), cause-specific mortality (8, 32%), natural-cause mortality (3, 12%), and specific morbidity-related mortality (6, 24%). Mortality estimates mostly obtained from the Global Burden of Disease study¹³⁷. Units ranged from total death counts, mortality rate per 100,000, DALYs and Years of Life Lost. Beyond morbidity and mortality, additional health outcomes included attributable hospital admissions, symptom onset, and high noise annoyance^{130,6}. Notably, the majority of HIAs assessed health impacts in adults. Only two HIAs (8%) assessed health outcomes in children, focusing on premature paediatric mortality¹²³ and asthma attack, respiratory symptoms, and bronchodilator usage¹³².

3.3.3 Exposure response functions and counterfactual scenarios

The most common sources of ERF were from epidemiological literature. Two HIAs obtained ERF estimates from local cohort studies, whilst one HIA estimated ERFs by atmospheric modelling with integrated risk function based on six meta-analyses 129. Only one HIA developed their own ERFs¹²¹, and these were applied in another HIA to estimate UHI impacts⁴⁶. Masselot et al. employed a three-stage modelling framework that applied daily time series temperature and mortality data, age-specific mortality, and composite indices of vulnerability to produce age- and city-specific ERFs¹²¹. The composite index of vulnerability was developed from distributed lag non-linear and meta-regression models and incorporated city size, proximity to green and blue space, and SE inequalities¹²¹. In general, ERFs were applied homogeneously to the adult study population. Exceptions included acute lower respiratory infection-specific ERF to infants under five years¹³², city-specific and age group-specific ERFs for temperature^{46,121}, and morbidity- and health endpoint-specific ERFs^{132,138,127,130}. There was variation in counterfactuals applied. Of the 13 HIAs (25%) that analysed health risk of PM_{2.5} exposure, five applied the same counterfactual 10μg/m³ based on the 2005 WHO guideline, whilst three applied the 2021 guideline of $5\mu g/m^3$ 126,128,129. For air pollution, counterfactuals ranged: for PM_{2.5} 2.4 - 35 $\mu g/m^3$ 126,139; ozone 54 - $160\mu g/m^3$ 139,140 ; $NO_2 \sim 3.78$ - $80\mu g/m^3$ and PM_{10} 5.8 - $40\mu g/m^3$ 130,132 . Two studies applied Chinese ambient air quality standards (CAAQS) as counterfactual scenarios 130,134, whereas Khomenko et al.'s study was the only one to apply the lowest measured concentration in the dataset as an additional counterfactual concentration⁵. Barboza et al. based counterfactuals on the WHO recommendation of universal access to green space (i.e., equal opportunity to access) within 300 m of residence, applying counterfactuals of 25% GA within 300m of residence and a target NDVI modelled for each city⁴⁷. Another HIA based in Europe estimated the mortality burden attributable to UHI by applying city-specific counterfactuals of exposure level scenarios without an UHI effect and estimated the impact on mortality by increasing tree coverage to 25%, 30%, and $40\%^{131}$. The only study to focus on road traffic noise health impacts applied WHO recommendation of 53dB, which remains the current guideline⁶.

3.3.4 Summary of findings

Global HIAs consistently reported cities in southeast Asian countries to experience the greatest pollutant concentrations and attributable health impacts worldwide^{129,131,141,142}. Inconsistent findings from HIAs conducted across the same years 2015 and 2020 in China reported ozone-related impacts increased by ~95% (5.05 x10⁶ DALYs) and 96% (7.64 x10⁵ DALYs) for all-cause and respiratory mortality¹³⁹, respectively, in contrast to ozone-attributable impacts reported to increase by 17% for all-cause mortality (133,415 deaths in 2015 to 156,173 deaths in 2020) and 17% for respiratory mortality (28,614 deaths in 2015 to 33,456 deaths in 2020). For NO₂, a global HIA reported highest NO₂-attributable deaths in South Asia (75,397 deaths) and Eastern Europe (46,840 deaths)¹⁴². Whereas within Europe, Khomenko et al. reported the highest NO₂ mortality burden was in Western and Southern European capital cities and applied local-level mortality rates; highest burden cities were Madrid (Spain), Antwerp (Belgium), and Turin (Italy)⁵.

Temporal trend HIAs revealed declining trends in PM_{2.5} concentrations and attributable mortality in China and globally^{126,128}. Southerland et al. reported the largest absolute decrease in mean urban population-weighted PM_{2.5} concentration between 2000 and 2019 was in Africa, decreasing by 18%¹²⁹. However, in certain regions, such as Luanda (Angola), there was an increase in PM_{2.5} concentrations and directional trends did not consistently align with trends in attributable mortality rates (an observation potentially explained by reported population growth). Another global temporal HIA covering 2000-2019 reported South and East Asia accounted for the highest proportion of global population ozone-attributable mortality in 2019, followed by Eastern Europe. However, this HIA reported divergent trends within South and East Asia; population-weighted ozone concentrations and mortality rates increased across all cities in South Asia, and decreased across all cities in East Asia¹⁴¹.

Additional insights from temporal trend analyses were the contribution of HIA parameters to health impact estimates. For ozone-attributed mortality, key global drivers were ozone concentrations and population, and for a few regions changes in baseline disease rates¹⁴¹. For PM_{2.5}-attributed mortality, changes in population growth and population ageing were the primary drivers in all regions¹²⁹. For specific cities across Africa, the Eastern Mediterranean, and Southeast

Asia, changes in baseline disease rates had the largest impact. Conversely, in the Western Pacific, the Americas, and Europe, reductions in $PM_{2.5}$ concentrations outweighed the influence of baseline disease rates 129 .

In addition to regional variation in exposure attributable health burden, there was heterogeneity among cities and age groups. In Europe, cities in Northern Italy were amongst cities with the highest mortality burden despite Italy not placing highest for PM_{2.5}-attributed mortality burden in country-level estimates⁵. Similarly in Europe, Barboza et al. reported 42,698 and 17,947 annual deaths could be prevented by increasing NDVI and %GA, respectively, and found unequal distribution of NDVI and %GA among and within cities⁴⁷. The only HIA to assess the impacts of non-optimal temperatures reported large variability in vulnerability across Europe¹²¹. The highest vulnerability was found in eastern European cities during extreme cold and heat and in age groups of over 85 years, which contributed over 60% to the total mortality burden. Annual excess deaths of 203,620 deaths (129 per 100,000 person years) were attributed to cold temperatures and 20,173 annual excess deaths (13 per 100,000 person years) attributed to heat. Iungman et al. found that increasing tree coverage to 30% can reduce city temperatures by 0.4°C and prevent almost 40% (2644 premature deaths) of 6700 premature UHI-attributable deaths⁴⁶. The only study to examine the effects of noise on health reported 11 million adults, of the estimated 60 million exposed to road traffic noise, to experience significant annoyance and 3608 IHD-deaths could have been prevented if compliance with WHO recommendations were achieved⁶. City comparative analysis was not possible due to inconsistencies in noise mapping methods.

3.4 Indicators

Identified indicators covered the key themes of this review: urban form, air pollution, temperature, green space, noise, and transport and mobility; in addition to climate change mitigation, which encompassed indicators of greenhouse gas emissions and climate change impact on trees. The indicators identified and methods employed, in addition to geographical coverage, spatial resolution, and data sources, are detailed in Table A1 of the Appendix. There was heterogeneity in spatial resolution of indicators; the greatest variation was amongst air pollution indicators, which ranged from 0.01° resolution to the coarsest resolution of NUTS3 level, a territorial unit defined by the European Commission Urban Audit that typically encompasses districts or boroughs²⁰³ (Table A1).

As part of a Lancet series on urban design, transport and health²⁰⁴, Boeing et al. developed an open-source framework with urban spatial indicators for measuring walkability and public transport access²⁰⁵. A total of 25 global cities were compared to elucidate the optimal urban design for promoting active travel³⁵. Applying the developed walkability index, Boeing et al. found compact cities had better walkability, whereas the worst performing cities for active travel were concentrated in more sprawled cities in high-income countries (HIC), such as Australia and the United States, consistent with previous findings 21,206. To add to the utility of these indicators, Cerin et al. sought to provide evidence-informed thresholds²⁰⁷. To meet the physical activity criteria of urban inhabitants having at least 80% probability of engaging in walking for transport, and WHO's target of at least 15% relative reduction in insufficient physical activity through walking²⁰⁸, neighbourhood targets associated with meeting one or both criteria were identified as: 5700 people per km², 100 intersections per km², and 25 public transport stops per km². Curvilinear associations of population, street intersection, and public transport densities with walking revealed less than a quarter of the studied population lived in neighbourhoods that reached these thresholds, with observed between-city differences; cities in Latin American upper-middleincome countries performed better than those in HIC. Another transport and mobility indicator that aimed to measure how conducive the urban environment is to active transport was the extent of bicycle network in a city²⁰⁹. Akande et al. utilised the UNECE-ITU Smart Sustainable Cities Framework to rank 28 European capital cities based on 32 sustainability indicators covering the thematic areas of economy, environment, and society and culture²¹⁰. Berlin (Germany) was ranked the most smart and sustainable city; indicators of bicycle network, wastewater treatment, and e-commerce had the greatest impact on ranking. Conversely, Sofia (Bulgaria) and Bucharest (Romania) were the lowest ranked cities, rankings were most influenced by indicators PM₁₀ emissions and protected terrestrial area (Table A1). Other novel indicators of urban form included access to urban services and amenities, considered proxies for opportunities and living standards within cities ^{211,205}.

Climate change mitigation indicators have the potential to advance understanding of how cities contribute to climate change, forecast impacts, and potential mitigation strategies. One indicator depicted the percentage change in greenhouse gas emissions between 2000 and 2020 at city-level, disaggregated by pollutant and sector (e.g., agriculture from livestock, soils, and waste burning, industry, residential, commercial, and off- and on-road transportation)²¹¹; in addition to a 20-year global warming potential and total emission summaries for 2000 and 2020 (Table A1). Pertinent to climate change urban mitigation strategies, the average annual greenhouse gas net flux from trees (per hectare of city area) was provided for a 21-year period, 2000 to 2021 (Table A1). This is complimented by an indicator of the same global coverage, which estimated the percentage of urban built-up land absent of tree cover²¹¹. Related temperature indicators included the percentage of built-up land with low surface reflectivity²¹¹. This enables identification of areas within a city that exhibit low solar reflectivity and thereby could derive significant benefit from the implementation of tree planting and green spaces.

Departing from commonly applied green space indicators that measure NDVI and %GA, novel methods for analysing green space included accessibility, quality, level of urban biodiversity, and the relation between green space and inequality (Table A1). Battiston & Schifanella developed a composite index for green space accessibility and exposed variation between-city levels; cities in Europe and Australia-Oceania had higher green space accessibility compared to regions in low- and middle-income countries and North America²¹². The index' sensitivity to parameterisation was evident from adjustment of metrics, such as level of inequality (defined by the GINI coefficient), resulting in different area rankings of green space accessibility. Complimentary work has aimed to quantify green space accessibility based on quality, defined as "high-amenity nature" 213. Ranking cities by amenity of accessible nature revealed higher population densities, although living generally further from nature, live closer to high-amenity nature compared to residents of lower urban population densities. Further advances for analysing green space were illustrated by Stowell et al. who applied cloud computing technology and analysis of remote sensing data to produce an urban greenness indicator dataset (measured by population-weighted peak and annual mean NDVI). Although an NDVI metric is not novel, 1000 global cities were classified based on level of greenness, climate zone, and HDI for the years of 2010, 2015, and 2020, which allows for temporal tracking of urban greenness – an attribute not available in other reviewed indicators²¹⁴ (Table A1).

4. Discussion

The purpose of this review was to synthesise evidence from large-scale urban studies that focused on the relation between urban structures, environmental exposures, and health and to identify future opportunities for urban health research. To achieve this, the research questions we sought to address were: what methodologies were applied in urban form, transport and mobility, and urban environmental health studies from 2003 to 2023? What are novel methods and indicators within urban environmental health research? What knowledge gaps necessitate further exploration?

Key findings from this review confirm the complex, intricate relation between the urban environment and health. This is evidenced from the discordant impacts from urban form variables on exposures and health. For example, compactness^{52,54}, high population density^{49,50,51,52}, green space^{57,62,69,47}, and extensive public transportation and active travel infrastructure^{49,53,73,207} were found to have a multitude of benefits, which promote health and well-being^{73,205,207}. Conversely, increasing density and compactness were associated with the trade-offs of reduced green space^{10,71}, accentuated UHI^{46,68}, and higher pollutant concentrations and exposure from congestion^{59,60}. Urban sprawl and fragmented city shapes were generally reported to have negative implications for city liveability⁵⁴ and health^{50,53}. This pertains to the '15-minute city' model, wherein all essential amenities for the urban residents' needs, such as health, socialisation and culture, are accessible by walking or cycling within a 15-minute radius²¹⁵. The strong correlation between urban sprawl and HDI could indicate sprawl has positive ramifications, owed to HDI incorporating life expectancy, educational attainment, and gross national income per capita²¹. Urban scaling laws offer a partial explanation, as linear urban scaling delineates that larger cities generate higher wages²¹⁶, consistent with findings of city size being the most influencing factor for urban sprawl⁵². Spatial analysis of urban form characteristics by Prieto-Curiel et al. demonstrated concomitant analysis is critical for understanding how urban shape and structures affect the functional and social aspects of urban living⁵¹.

An important inference from reviewed literature is the distinction between exposure and vulnerability, as certain less-exposed groups may have heightened vulnerability to the exposure under study. For example, sophisticated methods employed by Masselot et al. found the highest vulnerability to extreme cold and heat was in age groups of over 85 years¹²¹. Differential risk levels from extreme temperatures based on gender have been illustrated elsewhere, women aged 65 years and above and men below 65 years showed the highest vulnerability to hot temperatures²¹⁷. In Europe, groups of lower SES had lower MMT⁶¹, whilst in Latin America higher levels of poverty and income inequality were

associated with all-age MMT and higher cold MMT 58 . Inequality-driven variation in exposure levels was also present; reduced access to green space and therefore increased PM $_{2.5}$ -exposure was reported in lower income groups 62 .

4.1 What methodologies were applied in urban form, transport and mobility, and urban environmental health studies from 2003 to 2023?

There was heterogeneity across studies in methodologies, indicators, and city boundaries (Table 3 and 4). Sub-city units can vary in size and composition, and therefore, the boundaries of urban agglomerations can have a considerable effect on results, creating a potential bias towards larger cities¹⁰. Harmonised city definitions are a key challenge and may have contributed to contrasting results. To achieve cooling effects of urban green in Europe, tree cover of at least 16% was estimated to achieve a reduction of 1°C⁷², whilst an HIA study estimated 30% tree cover would be required to reduce temperatures by 0.4°C⁴⁶. Iungman et al. employed a city-level model⁴⁶, whilst Marando et al. utilised FUAs⁷², which encompass the surrounding community zone and suburban areas²¹⁸. Approaches to defining cities of the reviewed studies were based upon administrative boundaries⁵, functional definitions that rely on travel patterns and economic connections⁷², or morphological approaches that create shapes based on the extent of built-up or urbanised areas⁶²; the choice of definition typically depends upon research objectives. An operational city definition independent of context specificity would improve meaningful comparisons and transparency among studies.

The prevailing study design applied was cross-sectional or ecological (Table 3), which reflects a wider challenge in the field of requiring longitudinal studies and thus more robust causal inferences of the relation between urban design and health²¹⁹. This has further implications that the exposure-response relationships may be limited and therefore captured in analyses. For example, the link between urban land use, transport and mortality, and health is conceptually well understood; however, it lacks comprehensive quantitative evidence¹⁵.

In addition, the exposures under study may not accurately represent population exposure. In urban environmental health studies focused on green space, proximity was the primary exposure variable analysed. Exploration of the frequency²²⁰ that urban residents visit green space, potential variation in access between demographic subgroups²²⁰, and the quality and amenity can augment the understanding of population exposure and attributable health impacts. Research examining spatial inequalities in quality and accessibility of green space consistently report residents of more deprived neighbourhoods experience longer travel time to access green areas^{221,222}. In Brussels (Belgium), area-based deprivation levels were

associated with reduced satisfaction and authors identified factors that influence the use of green space, such as positive attributes of tranquillity and cleanliness and negative attributes of noise and lack of facilities²²¹. Further, none of the reviewed air pollutant studies explored indoor air pollution. Long-term exposure to indoor air pollutants can pose significant risk to human health²²³. A meta-analysis of burden of disease studies attributable to indoor air pollutants in China, found 9.5% more DALYs were attributable to indoor air pollutants compared to outdoor pollutants in 2017²²⁴. Given that people spend the majority of their time indoors, incorporation of indoor pollutant exposure estimates would ensure predicted health impacts are comprehensive and effectively advance the understanding of the magnitude of this exposure pathway. Novel materials for sensors, indoor air pollutionmonitoring systems, and smart homes show promise for advancing exposure and impact estimations of indoor air quality²²³.

In comparison to the other study designs employed, the HIA methodology can present distinct advantages; however, equally have distinct challenges. Within China, divergent estimates of ozone-attributable impacts for all-cause and respiratory mortality highlight the sensitivity of methodological choices 139,140. These respective studies applied the largest difference in counterfactuals of pollutant HIAs reviewed; Guan et al. 139 estimated impacts relative to 160µg/m³ whereas Zhang et al. 140 applied counterfactual of 54µg/m³. This may partially explain varied findings and highlights the significance of counterfactual scenario choices, in addition to the difficulty in study comparisons when different health outcomes are assessed (e.g., DALYs vs. deaths). Further, models used to calculate pollutant exposure levels are generally built using data representative of the average exposure and thus extremes in concentration response relationships are poorly understood. Investigation on the significance and choice of counterfactual scenarios was beyond the scope of this review; however, it highlights an important conjecture when conducting HIAs and interpreting results.

Additional insights from temporal trend HIAs were the ability to track impact over time and identify impact drivers of policies and exposure level changes. This can introduce the methodological challenge of the sensitivity ascribed to chosen years. Of the eight temporal studies, three included the year 2020 and thus the COVID-19 pandemic is likely to have influenced exposure levels and impact estimates 139,140,189. Whilst estimates of temperature-attributed health impact will be largely affected by a particularly hot year being included in analyses. Advances in available indicators that permit temporal tracking will improve the accuracy of temporal estimates and help mitigate this constraint. The only identified indicator that included temporal tracking was for green space availability, which may be

particularly useful in understanding climate change resilience of different urban green types²¹⁴.

4.2 What are novel methods and indicators within urban environmental health research?

The importance of studying local variance of environmental exposures and health impacts was illustrated and new methods and indicators show promise to this advancement. African cities with the same availability of green space were found to experience varying cooling effects during heat waves¹⁰. This was ascribed to varied distributions of green space within cities, suggesting availability is not the same as proximity and quality. This inference was corroborated by Barboza et al. whose sensitivity analyses suggested population distribution within cities influenced local differences of green space-attributable health impacts⁴⁷. To achieve a balance of dense and green cities, future research analysing the cooling effects of urban tree cover should consider the effects of climate change and urban green resilience ²²⁵. The greatest environmental benefits are considered to be provided by long-stature, mature trees and thus this is an important consideration for the time required and potential impact of climate change and UHI mitigation strategies²²⁵. Novel green space indicators of green space quality²¹³, level of amenity²⁰⁹, and urban biodiversity²¹¹ offer to advance this understanding. The latter may improve understanding of the ecological quality and species-richness; greater biodiversity closer to residence requires large urban connected patches and offers positive benefits on mental health and well-being¹⁰.

The emergence of cutting-edge technologies^{226,227} and advances in remote sensing and geospatial data sources present significant opportunities to enhance the comprehension of intricate urban health phenomena and the identification of key elements for sustainable urban design^{47,219}. These advancements hold the potential to address challenges related to diverse urban form metrics and definitions by leveraging geospatial data sources. These sources can improve the accuracy of population-weighted averages for obtaining overall urban metrics or enable the disaggregation of cities into neighbourhoods, thus facilitating better harmonisation. A key challenge will be effective translation of vast quantities of remote sensing and other spatial data sources into interpretable evidence of the complex spatial interactions²¹⁹; however, deep learning algorithms offer a promising solution to this challenge, through techniques such as semantic segmentation²²⁸.

Further applications of spatial data science and artificial-intelligent (AI)-driven tools for supporting sustainable urban development include agent-based modelling (ABM)²²⁹ and machine learning algorithms²²⁶. Motieyan et al. utilised an ABM to simulate the implementation of superblocks, an urban model that prioritises public space for active

transport and leisure and minimises motorised traffic²³⁰. By incorporating individual "agents" diverse behavioural patterns of local citizens were simulated which enabled anticipation of public opinion and acceptance of superblock implementation. Machine learning algorithms are enhancing predictions of environmental exposures, through methods such as integration of urban morphology data (e.g., topography and building height) into air quality forecasts²³¹. Woo Oh et al. trained deep learning models using meteorological data and urban texture factors (e.g., surface albedo) to develop temporal-and spatial-UHI models²³². The temporal UHI model that quantified the number of UHI hours rather than intensity, was found to be a better predictor of seasonal UHI predictions and therefore improved estimations of attributable heat-related mortality²³². Future urban research is likely to combine and harmonise data from various scales and sources, and leverage Spatial Data Science and AI-driven technologies to gain a more comprehensive understanding of urban dynamics, challenges and solutions.

4.3 What knowledge gaps necessitate further exploration?

A minority of studies included SE and demographic variables in analyses; however, observations from those that did confirm social determinants are an important avenue of future urban environmental health research. This would advance understanding of whether distinct urban form types can mitigate inequalities. Further, investigating inequalities within cities is particularly important in light of the limited knowledge of vulnerability drivers responsible for across city variation. These differences can be important; for example, differences in air pollution-attributable health burden are mostly due to differential levels of pollutants and can partly be explained by the pollutant chemical compositions²³³, whereas for other drivers, such as temperature, differences can be due to the level of vulnerability and resilience of the population²³⁴.

The paucity of demographic and SE data available at local-level was a commonly cited reason for not examining between population-group differences. This dearth of data both impedes the identification of health disparities and undermines the formulation of targeted and effective public health strategies for vulnerable populations. This is reflected in the literature from the limited evidence on gender-specific outcomes from urban adaptation intervention²³⁵. Females have been shown to experience multiple barriers to public transportation accessibility and thus this may influence female commuting choices and in turn exposure levels²³⁶. For HIAs, a methodological challenge central to the tendency of not stratifying estimates by gender and age is the lack of available sub-group ERFs. This reflects a gap in the underlying epidemiological evidence²³⁷. The lack of age-specific ERFs, particularly for populations under 20 years, may also be a by-product of the overemphasis

on $PM_{2.5}$ and O_3 pollutants in the literature. $PM_{2.5}$ - and O_3 -realated mortality impacts generally focus on the over 25-year-old population; however, in recent years more research has emerged for NO_2 -related health outcomes in paediatric populations ¹²³, ¹⁹⁵.

4.4 Limitations of urban environmental health studies

The pathways covered in this review are not an exhaustive list and do not cover all pathways to health. Additional pathways that hold relevance include social exclusion²³⁸, community severance²³⁸, stress²³⁸, and proximity to blue space²³⁹. There was an evident paucity of research investigating health burden attributed to noise pollution. The only noise study analysed impacts from road traffic noise; however, aircraft, rail and construction noise also have considerable health impacts²⁴⁰,²⁴¹. The household noise annoyance indicator may capture some of this exposure; however, the finest spatial resolution of NUTS3 restricts inferences for within city variability (Table A1). No studies incorporated climate change risk, which is a notable limitation for the HIAs that projected extreme heat and UHI.

The majority of studies applied regional-level estimates at city-level and assumed uniform distribution across cities, which discounts variability within and between cities. Commonly cited reasons for applying regional estimates were inconsistent data quality and availability at local-level and finer spatial resolutions^{123,125,130}; however, this can introduce the risk of uncertainty in local impact predictions. Approaches to mitigate this included extrapolating metrics from geographies with greater data coverage^{121,142} or excluding geographies from analyses⁴⁶. The latter pertains to the significant challenge of conducting HIAs in low- and middle-income countries²⁴². Few studies investigated within-city variation^{47,52,54,55,60}; the extent of which was also subject to data availability and quality⁴⁷. Ensuring fairness in data exploration and identification of local inequities necessitates robust and comprehensive datasets with uniform data collection at local-level. Central to this is collaboration across sectors, levels of government, and for researchers and practitioners to leverage open-data platforms²⁰⁵.

Applicable to all HIAs was the uncertainty attributed to ERFs and RRs. There was high variation in ERF data sources, which points to the general uncertainty surrounding the selection of the most accurate ERFs to apply (Table 4). For the majority of HIAs, the same ERFs were applied to the general population, which assumes equivalent risk. The paucity of sub-group ERFs that capture susceptibility merits that recommendations cannot be made for susceptible subpopulations.

4.5 Strengths and caveats of review

This was a scoping and not a formal systematic review, and therefore, aimed to provide a holistic overview of evidence from large-scale urban studies, rather than assess all evidence concerning a single relationship (e.g., air pollution and birth weight). Inclusion of additional health outcomes (e.g., mental health) in search terms may have identified further large-scale urban studies of relevance. Investigation of the interplay between urban environments and both established and emerging infectious diseases was beyond the scope of this review; however, these pathways have high relevance to the complex urban health ecosystem. Changes to land use, demographic shift patterns, and globalisation infrastructures have been identified as pivotal factors that influence infectious disease incidence and outbreak²⁴³. The COVID-19 pandemic illustrates the crucial role of governments and policies in managing infectious disease outbreaks, and highlights the inevitable trade-offs and conflicts encountered in planning strategies²⁴⁴. Enhancing understanding of the interconnection between urban form and infectious diseases holds significant prominence in both research and governmental priorities for urban and transport planning. The scope of exposures included in this review aligned with those of the UBDPolicy project⁴⁵; however, the caveat of additional pathways being excluded pertains to the broader challenge of prioritisation and resource constraints. Initiatives such as Urbanisation and Health Initiative²⁴⁵ led by the WHO, and the Urban Health Collaborative²⁴⁶ led by Drexel University, recognise the significance of investigating non-communicable and infectious diseases in tandem.

Strengths of this review include the expert consultation of relevant literature, which extended the scope of reviewed studies, and inclusion criterion of large-scale urban studies, which serves to increase the reliability and generalisability of results. Equally, this may have been a limitation as potential insights may have been missed from the 90-city inclusion criterion. Studies of fewer cities may have covered understudied regions and vulnerable populations. Not all geographical regions were covered (for example Australia and South Asia) and only English search terms were included in the literature search, exclusion of studies conducted in other languages may have contributed to the geographic distribution of studies and introduced bias in reported results. However, 22 studies were global in geographic coverage, this is considered a strength and may have mitigated potential exclusion bias. Further, PubMed was the sole electronic database articles were obtained from. This was due to PubMed's comprehensive coverage of health and biomedical research. Finally, examination of urban policies and affiliated impacts was beyond the scope of this review.

5. Conclusion and Future Perspectives

This scoping review aimed to synthesise evidence from large-scale urban studies to provide a state-of-the-art overview of the relation between urban structures, transport, environmental exposures, and health. The complexity of the urban ecosystem was evidenced and emphasises the need for a multi-faceted approach for elucidating the intricate urban environmental health pathways. Researchers should prioritise exploring associations at multiple spatial scales and resolutions, both within and between population groups. Identifying local disparities in exposure, vulnerability, and adaptation will require enhanced local-level data, open-source indicators, and shared consensus of best research practices. Advances in techniques, temporal trend analysis, and urban health and sustainability indicators show promising developments. To fully harness the potential of cities as key drivers of sustainable and healthy living, robust evidence should spearhead this change. Only then can policies and interventions realise the impact they set out to achieve.

Appendix

 Table A1
 Themes and indicators identified in this review.

Theme	Indicator	Description	Methods	Geographical coverage	Spatial resolution	Data Sources
	Recreational space per capita ²¹¹	The hectares of recreational space (open space for public use) per 1,000 people.	Recreational space data retrieved from OSM. OSM tags are employed to retrieve polygons that delineate areas of parks, nature reserves, commons, playgrounds, pitches, tracks, protected areas and national parks. Population data retrieved from WorldPop. The total recreational area within a jurisdictional boundary was divided by the population within the boundary per 1000 individuals.	Global		WorldPop ^{2/7} OpenStreetMap ^{2/8}
mroì nsdrU	Urban open space for public use ²¹ 1	The percentage of built-up area that is open space for public use.	Recreational space data retrieved from OSM. OSM tags are employed to retrieve polygons that delineate areas of parks, nature reserves, commons, playgrounds, pitches, tracks, protected areas and national parks. Definition of urban open or non-open space for each 10m pixel of built land derived using the built-up from ESA. The ratio of masked pixels representing open space to the total count of masked pixels was used to calculate the percentage of built area designated to open space.	Global	10m	OpenStreetMap ²⁴⁸ ESA WorldCover ²⁴⁹ Zanaga et al., 2021 ¹¹⁵
	Proximity to public open space ²¹¹	The percentage of the population within walking distance (400m) of public open space.	Utilised the gridded population (100m). Retrieved open space polygons from OSM buffered to 400m to derive recreation catchment areas. The population residing within the recreation catchment areas was determined and converted into a percentage by dividing that value by the total population of the area of interest.	Global	400m²	WorldPop ²⁴⁷ OpenStreetMap ²⁴⁸

400m²	500m	80km	0.01° (~1.1km)	NUTS3
Global	Global (25 cities)	Global	Global	Europe (28 cities)
Utilised 10m resolution tree cover and the gridded population (100m). A neighbourhood reduction technique utilising a circular kernel with a radius 400m was employed to the tree cover layer to determine the average percentage of tree cover within a 400m radius of each 10m pixel within the area of interest. The result is subsequently applied to filter the population layer, restricted to include 100m population pixels with an average tree cover of more than 10 percent within a 400m radius. The population within the 100m masked population layer is calculated and then converted to a percentage by dividing this figure by the total population of the area of interest.	Developed indicators for pedestrian network distance accessibility within a 500m radius, assessed for hexagonal grid cells and adjusted based on population percentage estimates.	The extracted data combines satellite monitoring of pollutant concentrations with amospheric modelling to estimate concentrations in close proximity to the Earth's surface. Reported the number of days in 2020 for each city that had near-surface concentrations of air pollutants that Exceeded WHO's guidelines for outdoor air pollutants. ²² 2.	Extracted data combines models of atmospheric mixing and chemistry with imagery analysis (from the Moderate Resolution Imaging Spectroradiometer and Sea-viewing Wide Field-of-view Sensor satellite instruments from NASA) to generate estimates of PM _{2.5} concentrations near the earth's surface, based on annual average concentrations for 2020. Each district's 2020 average PM _{2.5} concentration reported as a percentage of WHO's air quality guideline for annual exposure of 5µg/m³. The annual average is calculated over the area of the district. For example an average concentration of 15µg/m³ would be reported as 300 percent of the WHO guideline.	Calculated the sum of total days that PM $_{10}$ concentrations exceeded $50 \mu g/m^3$ for 2016 .
The percentage of the population with an average tree cover of greater than 10 percent within walking distance (400 m) of their homes.	Percentage of population living within 500m of a fresh food market, a convenience store, and public transport.	Annual number of days that air pollutants were above WHO air quality guidelines in 2020.	Annual mean PM2.5 concentration as a percentage of WHO's air quality guideline for annual exposure.	Number of days particulate matter PM ₁₀ concentrations exceed 50 µg/m³.
Proximity to tree cover ²¹¹	Distance to local amenities ²⁰⁵	High pollution days 211	Fine particulate matter exposure ²¹¹	Long-term exposure to PM _{1,0209}

Calculated the average annual concentration of NO $_{\rm 2}$ for 2016.	Tree cover with resolution of 10m applied. Built-up land data was obtained from ESA WorldCover and used to mask the tree cover layer. Counted the number of built area pixels that also had tree cover, and the total number of pixels with built areas. These two values were divided to determine the percentage of built land covered by trees. The percentage of tree cover was inverted to calculate the percentage of built-up land that lacked tree cover.	Calculated the anticipated number of days with maximum near-surface air temperatures exceeding 35%, for 2020 and 2050. Subsequently subtracted the 2020 estimate from the 2050 and divided this difference by the 2020 estimate and multiplied the result by 100. The resultant value is calculated from a probability distribution model.	LST calculated or each pixel in the area of interest using methods described elsewhere ²⁵⁶ and Landsat imagery. Average LST is calculated from a compilation of Landsat images that are cloud-masked. Images span from 2013 to 2022 and are selected for each year from the month with the highest temperature recorded, as determined by the ERA5 daily aggregates ²⁵⁴ . Average pixel LST were retrieved for built-up land cover areas, classified by the ESA WorldCover. Areas where the temperature exceeded the area average by 3°C or more were excluded to determine the proportion of build-up areas with elevated LST.	Used pixel-wise albedo values derived from Sentinel-2 using the algorithms defined elsewhere ²⁵⁷ . Annual mean albedo was calculated using doud-free pixels from 2021. Values for built-up land cover were obtained by applying the built-up class from the ESA WorldCover dataset as a masking tool. Pixels with values lower than 0.2 were excluded to determine the proportion of built-up area with reduced surface reflectivity.
Annual average concentration of NO2 ($\mu g/m^3$)	The percentage of built land without tree cover.	The anticipated extreme heat event hazard (measured as the number of days above 35°C in 2050) and the trend (indicated by the percentage change in the number of days exceeding 35°C between 2020 and 2050).	Percentage of built-up land with a high LST during the hot season (greater than or equal to 3°C above mean for built-up land).	The percentage of built-up land with low surface reflectivity.
Amual NO2 exposure ²⁷⁹	Builtland without tree cover ²¹¹	Extreme heat hazard ²¹¹	Land surface temperature ²¹¹	Surface reflectivity ²¹¹
			Temperature	

Open or green space $^{20.2}$	Percentage of population living within 500m of a public open space	For data obtained from OSM, followed tagging guidelines and collaborator feedback to classify open or green spaces. Determined the percentage of population residing within 500m of a public open space.	Global (25 cities)	500m	Global Human Settlement Layer ⁶⁵ OpenStreetMap ²³⁶
Urban greenness ²¹⁴	Population-weighted peak and annual mean NDVI. Gities grouped by urban greenness indicator, HDI and climate region.	Cities were selected based on population size of 500,000 or more. Calculated population-weighted peak and annual mean NDVI. Classified cities based on the greenness indicator, climate zone, and level of development. Repeated analyses for 2010, 2015, and 2020 to facilitate the tracking of urban greenery over time. Data provided in tabular and graphical format.	Global (1000 cities)	1km²	Landsat ²⁸⁸ Global gridded population ¹⁰² Global Human Settlement Urban Centre ³³ Köppen-Geiger climate classification system; ²⁹ United Nations ²⁰⁰
Green space accessibility ²¹⁴	Urban green space accessibility	For each identified city, constructed accessibility metrics by combining information on population estimates, spatial data on public green areas furtilesed for calculating walking distances within two cells in the city) and land cover of green space. Calculated accessibility indices of minimum distance (to closest public green area), exposure (overall size of available public green space), perperson (m² pre person of public green within walking distance from residential location). Evaluated the stability of each accessibility index through different parameterisations, including weighting by GINI coefficient, through application of Kendall rank correlation coefficient.	Global (1000 cities)	$1 \mathrm{km}^2$	Global gridded population:02 Global Human Settlement Urban Centre ⁹³ OpenStreetMap ²⁴⁸ World Cover data ⁸² Open Source Routing Machine engine ²⁶¹
Nature based well-being indicator ²¹³	Approximates the 'actual' subjective quality of nature near people's homes.	High-amenity nature ¹ identified by combining CORINE data on natural land use with clustered HSM data, on locations of attractive nature. Spatial cluster analysis conducted on HSM markers identifies natural areas that people have perceived as attractive. It produces a 250m² grid covering the observed country. The density of HSM markers is measured for each individual grid within the larger grid. Calculates population-weighted mean distance to high-amenity nature.	Netherlands, Germany and Denmark	250m²	European Environmental Agency (CORINE land cover dataset 2006) ¹⁰⁷ HSM database (Google Maps-based survey tool) ²⁶²
Percentage of amenity green space ²⁰⁹	Share of land dedicated to green urban areas, sports, and leisure facilities	Calculated the percentage of a city's total land area dedicated to green spaces, sports, and leisure facilities.	Europe (28 cities)	NUTS3	Urban Audit ¹⁴³

Calculated by dividing the number of bird species in built-up areas by the total number of bird species observed across all areas within the city. Built-up areas were delineated using data from the ESA. To estimate the saturation levels of species-area curves for the number of bird species, utilised research-grade observations of birds between 2016 and 2021. Calculations were conducted using the observations recorded on built-up land and all observations within city boundaries.	Determined the build-up area within a KBA located within a city, and divided this by the total KBA area within the city and multiplied the result by 100.	Calculated the percentage of a city's total land area that is designated as protected natural areas.	Calculated the percentage of the total population who reported being affected by noise.	Weekly trip flow information of 300 million people aggregated into weighted networks to identify hotspots of activity. Hotspots enabled analysis of hierarchical organisation in urban mobility and connection to city liveability. Spatial distribution patterns of hotspots capture differences in city organisation.
The percentage of bird species in all areas that were also observed in built-up areas.	The percentage of KBA in built up areas.	The percentage of land in a city designated as protected natural areas.	Proportion of population living in households considering that they suffer from noise	Quantifies the hierarchical organisation of urban mobility, considered a proxy for urban inhabitants' needs being met
Biodiversity of built-up areas ²¹¹	Biodiversity of built-up areas ²¹¹	Proportion of urban terrestrial area ²⁰⁹	Household noise annoyance ²⁰⁹	Urban mobility73

Calculated population density as the mean of the estimated population density within 1km of local walkable catchments. Street intersections were calculated as the average of the estimated intersection density within 1km of local walkable catchments. Daily living score was determined as the sum of binary access indicator scores to supermarkets, convenience stores, and public transport facilities, serving as a proxy for land use mix. Walkability index was calculated as the sum of x-scores, both within and between cities, for population density, intersection density, and daily living score.	Calculated the percentage of the population living within a 500m radius of any public transport stop.	Calculated the sum of lengths of dedicated bicyde paths.	Sectors include various agricultural activities, power generation, industry, transportation, and waste management. Using Google Earth Engine, the emissions within city administrative boundaries were calculated, disaggregating the data annually by sector in tonnes/year for 2000 and 2020. All emissions were converted to CO ₂ equivalent based on 20-year global warming potentials for a standardised measurement. The final indicator presents the percentage change in CO ₂ equivalent emissions from 2000 to 2020.
Combines population density, street intersection density, and daily living destinations in local neighbourhoods.	Percentage of population living within 500m of a frequently serviced public transport stop.	Length of dedicated cycle paths and lanes	The variation in annual greenhouse gas emissions (measured in CO ₂ equivalent (CO ₂ e) from the city area between 2000 and 2020, expressed as a percentage and broken down by pollutant type and sector.
Local walkability index ²⁰⁵	Public transport access ²⁰⁵	Length of bicycle network ²⁰⁹	Greenhouse gas emissions ²¹¹
			notiegitim əgnehə ətemilə

Google Earth Engine ²⁵⁶ Net Carbon Flux ²⁷⁰
30m
Global
Calculated the average annual carbon flux for each area, by assigning a zero value to pixels without carbon flux data. Mean carbon flux over the area was then calculated and divided by 21 to obtain an annual average for the 21-year period. This yielded an estimate of the average yearly net carbon flux per hectare for the area of interest. The entire geographical area, including non-forested regions, was employed for romainstainton, white total area serving as the emporage denominator. Negative numbers indicate net greenhouse gas removals, whereas positive values denote net emissions.
The average annual greenhouse gas net flux from trees (2001–21) per hectare (ha) of city area (negagrams [Mg] CO _{2e} /ha).
Climate change impact of trees ²¹ 1

Abbreviations: OpenStreetMap (OSM); European Space Agency (ESA); Copernicus Atmosphere Monitoring (CAM); National Aeronautics and Space Administration (NASA); Land Surface Temperature (LST); Normalised Difference Vegetation Index (NDVI); Human Development Index (HDI); Hotspotmonitor (HSM); Rey Biodiversity Indicator (KBA)

a High amenity defined as one of the following: ecosystem services (ESS), quality of cultural ESS (aesthetics), natural land uses.
b NUTS3: corresponds to small regions or local administrative units that include cities or urban areas²⁰⁰.
